      2. Variational variable elimination
Structured Variational Approximation

- Approximate inference based on belief propagation optimizes an approximate energy functional over the class of pseudo marginals
  - But the pseudo marginals do not correspond to a globally coherent joint distribution $Q$

- The structured variational approach aims to optimize the energy functional over a family $Q$ of coherent distributions $Q$
  - This family is chosen to be computationally tractable

  - Hence it is not sufficiently expressive to capture all of the information in $P_\Phi$
Inference as Maximization

• We address the following maximization problem in Structured Variational Inference:

\[
\text{Find } Q \in Q \\
\text{Maximizing } F[\tilde{P}_\Phi, Q] \\
\text{where } Q \text{ is a given family of distributions}
\]

• We use the exact energy functional \( F[P_\Phi, Q] \)

  • which satisfies \( D(Q||P_\Phi) = \ln Z - F[P_\Phi, Q] \)

  – Thus maximizing the energy functional corresponds directly to obtaining a better approximation to \( P_\Phi \) in terms of \( D(Q||P_\Phi) \)
Parameter of Maximization

• Main parameter in maximization problem is choice of family $Q$
  – This choice introduces a trade-off
    • Families that are simpler, i.e., BNs and MNs of small tree width allow more efficient inference
    • If $Q$ is too restrictive then it cannot represent distributions that are good approximations of $P_{\Phi}$
      – Giving rise to a poor approximation $Q$

• Family is chosen to have enough structure
  – Hence called **structured variational approximation**
    • Variational calculus since we maximize over functions
    • Unlike belief propagation guaranteed to lower bound the log-partition function and guaranteed to converge
The Mean Field Approximation

- First approach considered is the mean field approximation
- It resembles the Bethe approximation to the mean field functional

The resulting algorithm performs message passing where the messages are over single variables
  - The form of the updates is different
Mean Field Class of Distributions

• The mean field algorithm finds the distribution $Q$ which is closest to $P_\Phi$ in terms of $D(Q||P_\Phi)$

• within the class of distributions representable as the product of independent marginals

$$Q(\chi) = \prod_i Q(X_i)$$

• Trade-off:
  – A fully factored distribution loses information
  – But we can easily evaluate any query
    • By a product of terms that involve variables in query
  – To represent $Q$ we only need marginals of variables
Derivation of Mean Field Algorithm

• Recalling that

\[ D(Q \| P_\Phi) = \ln Z - F(\tilde{P}, Q) \]

Minimizing \( D \) is equivalent to maximizing \( F \)

• We consider the energy functional in the form

\[ F[\tilde{P}, Q] = E_Q[\ln \tilde{P}(\chi)] + H_Q(\chi) = \sum_{\phi \in \Phi} E_Q[\ln \phi] + H_Q(\chi) \]

– where \( Q \) has the form of

\[ Q(\chi) = \prod_i Q(X_i) \]

• We then characterize fixed points for each \( Q \)
• Thereby derive an iterative algorithm to find such fixed points
  – In fixed point iteration \( x_{n+1} = f(x_n), \ n=0,1,2,.. \)

A functional takes a function as input and produces a value as output, e.g., entropy

Example of fixed pt:
Newton’s roots

\[ x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)} \]
Computing the Energy Functional

- The functional contains two terms:
  \[ F[\tilde{P}_\phi, Q] = \sum_{\phi \in \Phi} E_Q[\ln \phi] + H_Q(\chi) \]

  1. The first is a sum of terms of the form \( E_{U_\phi \sim Q}[\ln \phi] \) where we need to evaluate

\[
E_{U_\phi \sim Q}[\ln \phi] = \sum_{u_\phi} Q(u_\phi) \ln \phi(u_\phi)
= \sum_{u_\phi} \left( \prod_{x_i \in U_\phi} Q(x_i) \right) \ln \phi(u_\phi)
\]

- We can use the form of \( Q \) to compute \( Q(u_\phi) \) as a product of marginals (performed in linear in no. of values of \( U_\phi \))

  1. The term \( H_Q(\chi) \) also decomposes in this case

\[
H_Q(\chi) = \sum_i H_Q(X_i)
\]

- Thus energy functional is a sum of expectations
  - Each one over a small set of variables
Complexity of Energy Functional

- Energy functional for a fully factored distribution $Q$ can be written as a sum of expectations:

$$F[\tilde{P}_\phi, Q] = \sum_{u_\phi} \left( \prod_{X_i \in U_\phi} Q(x_i) \ln \phi(u_\phi) \right) + \sum_i E_Q \left[ \ln \frac{1}{Q(X_i)} \right]$$

  - Each one over a small set of variables
  - Complexity depends on size of the factors in $P_\phi$
    - Not on the topology of the network
  - Thus the energy functional in this case can be represented/manipulated effectively
    - even when exact inference requires exponential time
Ex: Mean field energy for 4x4 grid

- Energy functional has the form

\[
F[\tilde{P}_\phi, Q] = \sum_{i \in \{1,2,3\}, j \in \{1,2,3,4\}} E_Q[\ln \phi(A_{i,j}, A_{i,j+1})] + \sum_{i \in \{1,2,3,4\}, j \in \{1,2,3\}} E_Q[\ln \phi(A_{i,j}, A_{i,j+1})] + \sum_{i \in \{1,2,3,4\}, j \in \{1,2,3,4\}} H_Q(A_{i,j})
\]

- It involves only expectations over single variables and pairs of neighboring variables

- The expression has the same form for an \( n \times n \) grid

  - Thus although tree width for an \( n \times n \) grid is exponential in \( n \), the energy functional can be computed in \( O(n^2) \), i.e., linear in no. of variables \( n^2 \)
Maximizing Energy Functional: Fixed-point Characterization

- Task is to find distribution $Q$ for which energy functional is maximized.

Mean-Field

Find $Q \in Q$

Maximizing $F[\tilde{P}_\Phi, Q]$

Subject to $Q(\chi) = \prod_i Q(X_i)$

$\sum_{x_i} Q(x_i) = 1 \ \forall i$

- We use Lagrange multipliers to characterize stationary points of $F[\tilde{P}_\Phi, Q]$

- The structure of $Q$ allows us to consider the optimal value of each component given the rest.
Mean Field Theorem: maximum of $Q(X_i)$

**Thm:** $Q(X_i)$ is a local max of Mean-Field given $\{Q(X_j)\}_{j \neq i}$ iff

\[
Q(x_i) = \frac{1}{Z_i} \exp \left\{ \sum_{\phi \in \Phi} E_{\chi \cdot \phi} [\ln \phi | x_i] \right\}
\]

where $Z_i$ is a local normalizing constant and $E_{\chi \cdot Q} \ln \phi | x_i$ is the conditional expectation given value $x_i$.

**Proof:**

1. Objective function is:

\[
F[\tilde{P}_\phi, Q] = \sum_{\phi \in \Phi} E_Q[\ln \phi] + H_Q(\chi)
\]

2. Restricting attention to $Q(X_i)$ terms:

\[
F_i [Q] = \sum_{\phi \in \Phi} E_{U \cdot Q}[\ln \phi] + H_Q(X_i)
\]

3. To optimize $Q(X_i)$ define Lagrangian of terms in $F[\tilde{P}_\phi, Q]$

\[
L_i [Q] = \sum_{\phi \in \Phi} E_{U \cdot Q}[\ln \phi] + H_Q(X_i) + \lambda (Q(x_i) - 1)
\]

4. For derivatives use lemma:

\[
\frac{\partial}{\partial Q(x_i)} F[\tilde{P}_\phi, Q] = \frac{\partial}{\partial Q(x_i)} E_{U \cdot Q}[f(U)]
\]

5. Using lemma & standard derivatives of entropy:

\[
\frac{\partial}{\partial Q(x_i)} L_i = \sum_{\phi \in \Phi} E_{\chi \cdot Q} [\ln \phi | x_i] - \ln Q(x_i) - 1 + \lambda
\]

6. Set derivatives to 0 & rearrange:

\[
\ln Q(x_i) = 1 + \sum_{\phi \in \Phi} E_{\chi \cdot Q} [\ln \phi | x_i]
\]

7. Take exponents of both sides, and $\lambda$ constant.

8. **Solution:** $Q(x_i)$ is maximum since $\sum E_{U \phi}$ is linear & $H_Q$ is concave.
Corollary of Mean-Field Theorem

• To convert

\[ Q(x_i) = \frac{1}{Z_i} \exp \left\{ \sum_{\phi \in \Phi} E_{X \phi} \left[ \ln \phi | x_i \right] \right\} \]

into update algorithm

– Observe that if \( X_i \notin \text{Scope}(\phi) \) then

\[ E_{U_\phi \sim Q} \left[ \ln \phi | x_i \right] = E_{U_\phi \sim Q} \left[ \ln \phi \right] \]

• i.e., expectation of such factors are independent of \( x_i \)

Cor. In mean field approx. \( Q(X_i) \) is a local maximum iff

\[ Q(x_i) = \frac{1}{Z_i} \exp \left\{ \sum_{\phi: X_i \in \text{Scope}(\phi)} E_{U_\phi \sim (X_i)} \left[ \ln \phi(U_\phi, x_i) \right] \right\} \]

• This representation shows that \( Q(X_i) \) have to be consistent with expectation of the potentials in which it appears

– In grid network, it implies that \( Q(A_{i,j}) \) is the product of four terms

\[ Q(a_{i,j}) = \frac{1}{Z_{i,j}} \exp \left\{ \sum_{a_{i,j}} Q(a_{i,j}) \ln \left( \phi(a_{i,j}, a_{i,j}) \right) + \sum_{a_{i-1,j}} Q(a_{i-1,j}) \ln \left( \phi(a_{i-1,j}, a_{i,j}) \right) + \sum_{a_{i,j-1}} Q(a_{i,j-1}) \ln \left( \phi(a_{i,j-1}, a_{i,j}) \right) + \sum_{a_{i,j+1}} Q(a_{i,j+1}) \ln \left( \phi(a_{i,j+1}, a_{i,j}) \right) \right\} \]

Each term is a geometric average of one of the potentials involving \( A_{i,j} \)
From Mean Field to Update Algorithm

- We now have tools for algorithm to find max $\mathbb{E}[\tilde{P}_\phi, Q]$.
  - They are: $Q(x_i) = \frac{1}{Z_i} \exp \left\{ \sum_{\phi \in \text{supp}(\phi)} E_{(U_\phi, x_i) \sim \phi} \left[ \ln \phi(U_\phi, x_i) \right] \right\}$ and $Q(a_{i,j}) = \frac{1}{Z_{i,j}} \exp \left\{ \sum_{a_{i,j}} Q(a_{i,j}) \ln \phi(a_{i,j}, a_{i,j}) + \sum_{a_{i,j}} Q(a_{i,j}) \ln \phi(a_{i,j}, a_{i,j}) + \sum_{a_{i,j}} Q(a_{i,j}) \ln \phi(a_{i,j}, a_{i,j}) + \sum_{a_{i,j}} Q(a_{i,j}) \ln \phi(a_{i,j}, a_{i,j}) \right\}$
  - Term within exponential
    - is easily evaluated by
      - interactions between neighbors of $A_{i,j}$ and values they can take
  - RHS has expectations of variables not involving $X_i$
  - Resulting $Q(X_i)$ is optimal given all other values
    - Simply evaluate exponent terms for each value of $x_i$,
      normalize results to sum to 1 and assign them to $Q(X_i)$
    - Consequently we reach optimal $Q(X_i)$ in one easy step
  - To optimize relative to all variables, embed step in iterated coordinate ascent algorithm
    - Optimize single marginal at a time, given fixed choices of others
Algorithm: Mean-Field Approximation

- **Procedure** Mean-Field \( \{ \Phi, \ P_\Phi \} \)
  
  \( Q_0 \) ///initial choice of \( Q \)
  
  1. \( Q \leftarrow Q_0 \)
  
  2. \( \text{Unprocessed} \leftarrow \chi \)
  
  3. **while** \( \text{Unprocessed} \neq \emptyset \)
  
  4. Choose \( X_i \) from \( \text{Unprocessed} \)
  
  5. \( Q_{\text{old}}(X_i) \leftarrow Q(X_i) \)
  
  6. **for** \( x_i \in \text{Val}(X_i) \) **do**
  
  7. \( Q(x_i) \leftarrow \exp \left\{ \sum_{\phi \in \text{Scope}\{\Phi\}} E_{(U_{\Phi \setminus \{X_i\}} \cdot \Phi)} \left[ \ln \phi(U_{\Phi \setminus \{X_i\}}, x_i) \right] \right\} \)
  
  8. Normalize \( Q(X_i) \) to sum to one
  
  9. **if** \( Q_{\text{old}}(X_i) \neq Q(X_i) \) **then**
  
  10. \( \text{Unprocessed} \leftarrow \text{Unprocessed} \cup (\bigcup_{\phi \in \text{Scope}\{\Phi\}} \text{Scope}\{\phi\}) \)
  
  11. \( \text{Unprocessed} \leftarrow \text{Unprocessed} - \{X_i\} \)
  
- **return** \( Q \)
Observations about Algorithm

• A single optimization of $Q(X_i)$ does not suffice.
  – A subsequent modification of another marginal $Q(X_i)$ may result in a different optimal parameterization for $Q(X_i)$
  – Thus algorithm repeats the steps until convergence

• Each iteration of Mean-Field results in a better approximation $Q$ to the target density $P_\Phi$ guaranteeing convergence

• The convergence points are local maxima
  – Not necessarily global
Ex: Mean-Field Energy Functional

- A distribution $P_\Phi$
  
  $P(a, b) = 0.5 - \epsilon$ if $a \neq b$
  
  $P(a, b) = \epsilon$ if $a = b$

  - Which is a Noisy XOR

- Mean field Energy $F[\tilde{P}_\Phi, Q]$ |

- As XOR, $P_\Phi$ cannot be approximated by a product of marginals

- But energy potential surface has two peaks at $a \neq b$
Structured Approximations

• Although Mean Field Algorithm provides an easy approximation method, we are forcing $Q$ to be a very simple distribution
  – All variables being independent of each other in $Q$ leads to very poor approximations

• If we use a $Q$ that can capture some dependencies in $P_\Phi$ we can get a better approximation
  – Thus explore approximations inbetween mean field and exact inference
  – Using network structures of different complexity
Fixed-point characterization

• Focus on using MNs instead of BNs
• Parameterized Gibbs distributions
  – Not restricted to factors over maximal cliques
• Form of variational approximation
  – $Q$ is from a Gibbs parametric family
  – We are given a set of potential scopes $\{C_j \subseteq \chi : j = 1, \ldots, J\}$
  – We choose an approximation $Q$ that has the form
    \[
    Q(\chi) = \frac{1}{Z_Q} \prod_{j=1}^{J} \psi_j
    \]
    • where $\psi_j$ is a factor with scope $\text{Scope}[\psi_j] = C_j$
Ex: Grid Network

- Given:

  - There are many possible approximate network structures, two of them are:

    Both a collection of independent chain structures
    
    Inference is linear
    
    Not much worse than mean field
Method of Structured Variational

• Decide on form of potentials $\phi$ for family $Q$

• We consider energy functional for a distribution $Q$ in this family
  – Characterize the stationary points of functional
  – Use those to derive iterative optimization algorithm

• Evaluating terms that involve $E_{U_\phi,Q}[\ln \phi]$ requires performing expectations wrt variables in $\text{Scope}[\phi]$
  – Complexity of expectation depends on structure of approximating distribution
  • Assume we can solve this problem using exact inference
