Topics in Monte Carlo Methods

1. Sampling and Monte Carlo Methods
2. Importance Sampling
3. Markov Chain Monte Carlo Methods
4. Gibbs Sampling
5. Mixing between separated modes
Importance Sampling: Choice of $p(x)$

- Sum of integrand to be computed:
  
  **Discrete case**
  \[ s = \sum_{x} p(x) f(x) = E_p \left[ f(x) \right] \]

  **Continuous case**
  \[ s = \int p(x) f(x) \, dx = E_p \left[ f(x) \right] \]

- An important step is deciding which part of the integrand has the role of the probability $p(x)$
  - from which we sample $x^{(1)}, \ldots, x^{(n)}$

- And which part has role of $f(x)$ whose expected value (under the probability distribution) is estimated as

\[
\hat{s}_n = \frac{1}{n} \sum_{i=1}^{n} f(x^{(i)})
\]
Decomposition of Integrand

• In the equation
  \[ s = \sum_x p(x)f(x) \]
  \[ s = \int p(x)f(x) \, dx \]

• There is no unique decomposition because.

\[ p(x)f(x) \] can be rewritten as

\[ p(x)f(x) = q(x) \frac{p(x)f(x)}{q(x)} \]

– where we now sample from \( q \) and average

\[ \frac{p(x)f(x)}{q(x)} \]

– In many cases the problem
  \[ s = \int p(x)f(x) \, dx \]

is specified naturally as expectation of \( f(x) \) given distribution \( p(x) \)

• But it may not be optimal in no of samples required
Difficulty of sampling from $p(x)$

- Principal reason for sampling $p(x)$ is evaluating expectation of some $f(x)$

$$E[f] = \int f(x)p(x) \, dx$$

- Given samples $x^{(i)}, i=1,\ldots,n,$ from $p(x)$, the finite sum approximation is

$$\hat{f} = \frac{1}{n} \sum_{i=1}^{n} f(x^{(i)})$$

- But drawing samples $p(x)$ may be impractical
Using a proposal distribution

Rejection sampling uses a proposal distribution

- Determining if sample is in shaded area
  - Generate two random numbers
    - \( z_0 \) from \( q(z) \)
    - \( u_0 \) from uniform distribution \([0, kq(z_0)]\)
  - This pair has uniform distribution under the curve of function \( kq(z) \)
  - If \( u_0 > \tilde{p}(z_0) \) the pair is rejected otherwise it is retained
  - Remaining pairs have a uniform distribution under the curve of \( p(z) \) and hence the corresponding \( z \) values are distributed according to \( p(z) \) as desired
Importance sampling retains samples

• **Importance sampling uses:**
  – A proposal distribution—like rejection sampling
    • where samples not matching conditioning are rejected
    • But all samples are retained
  – Assumes that for any $x$, $p(x)$ can be evaluated
Determining Importance weights

- **Samples** \( \{x^{(i)}\} \) from simpler distribution \( q(x) \)

\[
E[f] = \int f(x) p(x) \, dx
= \int f(x) \frac{p(x)}{q(x)} q(x) \, dx
= \frac{1}{n} \sum_{i=1}^{n} \frac{p(x^{(i)})}{q(x^{(i)})} f(x^{(i)})
\]

- **Samples** are weighted by ratios

\[
r_i = \frac{p(x^{(i)})}{q(x^{(i)})}
\]

- Known as importance weights
  - Which corrects the bias introduced by wrong distribution
Importance Sampling

- Better way to compute integrals than rejection
- Sample from a distribution $q(x)$ and reweigh the samples in a principled way

$$E_{x \sim p}[f(x)] = \sum_x f(x)p(x)$$
$$= \sum_x f(x) \frac{p(x)}{q(x)} q(x)$$
$$= E_{x \sim q}[f(x)w(x)]$$
$$\approx \frac{1}{M} \sum_{m=1}^{M} f(x^{(m)})w(x^{(m)})$$

- where $w(x) = \frac{p(x)}{q(x)}$ and samples $x^{(m)}$ drawn from $q$
- So take samples from $q(x)$ and reweigh them with $w(x)$
  - But $p(x)$ is intractable, but there is a solution

This can be treated as computing expectation of $p(x)/q(x)$ wrt $q(x)$
Case of Uniform $q(x)$

If $\chi = Z \cup E$ then to compute marginal $p(E=e)$

\[
p(E = e) = \mathbb{E}_{z \sim p}[p(e \mid z)] \\
= \mathbb{E}_{z \sim q}[\frac{p(e, z)}{q(z)}] \\
= \mathbb{E}_{z \sim q}[we(z)] \\
\approx \frac{1}{M} \sum_{m=1}^{M} we(z^{(m)})
\]

where $w_e(z) = p(e,z)/q(z)$ is the sample weight

\[
p(e) = \sum_z p(e \mid z)p(z)
\]

\[
p(e) = \sum_z p(e \mid z)p(z) \frac{q(z)}{q(z)}
\]

Unlike rejection sampling importance sampling will use all samples
Dealing with intractable $p(x)$

- Importance sampling seems to assume that we are able to compute the importance weight $w(x) = \frac{p(x)}{q(x)}$.
- While $q(x)$ is left as our choice, $p(x)$ may be intractable.
- We can use the unnormalized $\tilde{p}(x)$ as shown next.
Unnormalized Importance sampling

• Define weight using unnormalized distribution

\[ w(x) = \frac{\tilde{p}(x)}{q(x)} \]

• Then

\[ E_{x-q} \left[ w(x) \right] = \sum_x q(x) \frac{\tilde{p}(x)}{q(x)} = \sum_x \tilde{p}(x) = \alpha \]

• And

\[
E_{x-p} \left[ f(x) \right] = \sum_x p(x)f(x) \\
= \sum_x q(x)f(x) \frac{p(x)}{q(x)} \\
= \frac{1}{\alpha} \sum_x q(x)f(x) \frac{\tilde{p}(x)}{q(x)} \\
= \frac{1}{\alpha} E_{x-q} \left[ f(x)w(x) \right] \\
= \frac{E_{x-q} \left[ f(x)w(x) \right]}{E_{x-q} \left[ w(x) \right]}\
\]

Therefore, we can determine \( E_{x-p}[f(x)] \) using samples drawn from \( q \) as follows:

\[
E_{x-p} \left[ f(x) \right] = \frac{\sum_m f(x[m])w(x[m])}{\sum_m w(x[m])}
\]
Normalized Importance Sampling

- Unnormalized importance sampling unsuitable for conditional probabilities

\[
P(X_i = x_i \mid E = e) = \frac{P(X_i = x_i, E = e)}{P(E = e)}
\]

- With unnormalized we could estimate numerator as

\[
P(X_i = x_i, E = e) = \sum_z \delta(z)p(e, z)
= \sum_z \delta(z)w_e(z)q(z)
= \mathbb{E}_{z \sim q}[\delta(z)w_e(z)]
\approx \frac{1}{M} \sum_{m=1}^{M} \delta(z^{(m)})w_e(z^{(m)})
\]

- and denominator from samples as

\[
P(E = e) \approx \frac{1}{M} \sum_{m=1}^{M} w_e(z^{(m)})
\]

Which is shown on Slide 16

- Separate Numerator & Denominator compounds errors

  » If Numerator is an underestimate, Denominator is an overestimate, overall result is a severe underestimate
Using same set of samples

- If we use the same set of $M$ samples $z^1,..z^M \sim q$
  - For both numerator and denominator, we avoid this issue of compounding errors
  - Final form of normalized importance sampling is
    \[
    \hat{P}(X_i = x_i \mid E = e) = \frac{\frac{1}{T} \sum_{t=1}^{T} \delta(z^t) w_e(z^t)}{\frac{1}{T} \sum_{t=1}^{T} w_e(z^t)}
    \]
    where
    \[
    \delta(z) = \begin{cases} 
    1 & \text{if } z \text{ is consistent with } X_i = x_i \\
    0 & \text{otherwise}
    \end{cases}
    \]
    and $w_e(z) = p(e,z) / q(z)$

- However, it is biased, for $M=1$
  \[
  \mathbb{E}_{z \sim q}[\hat{P}(X_i = x_i \mid E = e)] = \mathbb{E}_{z \sim q}[\delta(z)] \neq P(X_i = x_i \mid E = e)
  \]
  - Fortunately both numerator and denominator are unbiased so the result is asymptotically unbiased
  \[
  \lim_{T \to \infty} \mathbb{E}_{z \sim q}[\hat{P}(X_i = x_i \mid E = e)] = P(X_i = x_i \mid E = e)
  \]
Derivation of Optimal $q^*(x)$

- Any Monte Carlo estimator can be transformed into an importance sampling estimator using

$$\hat{s}_p = \frac{1}{n} \sum_{i=1}^{n} f(x^{(i)})$$

$$\hat{s}_q = \frac{1}{n} \sum_{i=1,x^{(i)}_q}^{n} \frac{p(x^{(i)})f(x^{(i)})}{q(x^{(i)})}$$

- It can be readily seen that the expected value of the estimator does not depend on $q$:

$$E_q[\hat{s}_q] = E_q[\hat{s}_p] = s$$

- The variance of an importance sampling estimator is sensitive to the choice of $q$. The variance is

$$\text{Var}[\hat{s}_p] = \text{Var}\left[\frac{1}{n} \frac{p(x)f(x)}{q(x)}\right]$$

- The minimum variance occurs when $q$ is

$$q^*(x) = \frac{p(x)f(x)}{Z}$$

- where $Z$ is the normalization constant chosen so that $q^*(x)$ sums or integrates to one
Choice of suboptimal \( q(x) \)

- Any choice of \( q \) is valid and \( q^* \) is the optimal one (yields minimum variance)
- Sampling from \( q^* \) is usually infeasible
- Other choices of \( q \) can be feasible, reducing variance somewhat
Biased Importance Sampling (BIS)

• Another approach is BIS
  – Has advantage of not requiring normalized $p$ or $q$
  – For discrete variables, BIS estimator is

\[
\hat{s}_{BIS} = \frac{\sum_{i=1}^{n} \frac{p(x^{(i)})}{q(x^{(i)})} f(x^{(i)})}{\sum_{i=1}^{n} \frac{p(x^{(i)})}{q(x^{(i)})}}
= \frac{\sum_{i=1}^{n} \frac{p(x^{(i)})}{q(x^{(i)})} f(x^{(i)})}{\sum_{i=1}^{n} \frac{\tilde{p}(x^{(i)})}{\tilde{q}(x^{(i)})}}
= \frac{\sum_{i=1}^{n} \frac{\tilde{p}(x^{(i)})}{\tilde{q}(x^{(i)})} f(x^{(i)})}{\sum_{i=1}^{n} \frac{\tilde{p}(x^{(i)})}{\tilde{q}(x^{(i)})}},
\]

where $p^\wedge$ and $q^\wedge$ are unnormalized forms of $p$ and $q$
and $x^{(i)}$ are samples from $q$
Effect of choice of $q$

- Good $q$ → efficient Monte Carlo estimation
- Poor choice of $q$ → efficiency much worse
  - Looking at $\text{Var}[\hat{s}_p] = \text{Var} \left[ \frac{1}{n} \frac{p(x)f(x)}{q(x)} \right]$ if there are samples for which $\frac{p(x)f(x)}{q(x)}$ is large then the variance of the estimator can get large
    - Happens when $q(x)$ is tiny while neither $p(x)$ or $q(x)$ is small enough to cancel it
  - The $q$ distribution is usually chosen to be a very simple distribution so that it is easy to sample from
    - When $x$ is high dimensional this simplicity causes it to match $p$ of $p|f|$ poorly
    - Very small or very large ratios are possible when $x$ is high dimensional
Importance sampling in Deep learning

• Used in many ML algorithms incl. deep learning

• Examples
  – To accelerate training in neural language models with large vocabulary
    • Other neural nets with large no of outputs
  – Estimate partition function (normalize prob. distribution)
  – Estimate log-likelihood in deep directed models such as variational autoencoder
  – Estimate gradient in SGD where most of the cost comes from a small no of misclassified samples
    • Sampling more difficult examples can reduce variance of gradient
Importance Sampling and VAE

To evaluate the goodness of a VAE we decide to use Bayesian Model comparison

\[
Pr(M|D) = \frac{Pr(D|M) Pr(M)}{Pr(D)}
\]

Thus for each model \( M \) we need

\[
P_M(X) = \int p_M(X|z)p(z)dz \approx \frac{1}{N} \sum_{i=1}^{N} p_M(x|z_i), \quad z_i \sim \mathcal{N}(0, 1)
\]

Use importance sampling with \( q \) being scaled and shifted Gaussians from our encoder

\[
P_M(X) = \int p_M(X|z)p(z)dz \approx \frac{1}{N} \sum_{i=1}^{N} \frac{p_M(X|z_i)p_{\mathcal{N}(0,1)}(z_i)}{q_{\mathcal{N}(\mu(X), \sigma(X))}(z_i)}, \quad z_i \sim \mathcal{N}(\mu(X), \sigma(X))
\]

If $T_j$ are independent exponentially distributed with means as given, then completion time is a random variable with mean $E_{10}=18$ and a long tail to the right.

If there is a severe penalty for $E_{10}>70$, direct simulation with $n=10,000$ indicates $E_{10}>70$ happened only 2 times.

Importance sampling gets a better estimate of this probability with $\lambda = 4 \theta$ and $n = 10,000$ gave $\hat{\mu}_\lambda = 2.02 \times 10^{-5}$.
