Importance of Linear Algebra in ML

But what is RIGHT? And is that enough? (Image: Machine Learning, XKCD)
Topics in Linear Algebra for ML

- Why do we need Linear Algebra?
- From scalars to tensors
- Flow of tensors in ML
- Matrix operations: determinant, inverse
- Eigen values and eigen vectors
- Singular Value Decomposition
- Principal components analysis
What is linear algebra?

• Linear algebra is the branch of mathematics concerning linear equations such as

\[ a_1 x_1 + \cdots + a_n x_n = b \]

– In vector notation we say \( a^T x = b \)
– Called a linear transformation of \( x \)

• Linear algebra is fundamental to geometry, for defining objects such as lines, planes, rotations

Linear equation \( a_1 x_1 + \cdots + a_n x_n = b \) defines a plane in \((x_1, \ldots, x_n)\) space
Straight lines define common solutions to equations
Why do we need to know it?

- Linear Algebra is used throughout engineering
  - Because it is based on continuous math rather than discrete math
    - Computer scientists have little experience with it
- Essential for understanding ML algorithms
  - E.g., We convert input vectors \((x_1, \ldots, x_n)\) into outputs by a series of linear transformations
- Here we discuss:
  - Concepts of linear algebra needed for ML
  - Omit other aspects of linear algebra
Linear Algebra Topics

– Scalars, Vectors, Matrices and Tensors
– Multiplying Matrices and Vectors
– Identity and Inverse Matrices
– Linear Dependence and Span
– Norms
– Special kinds of matrices and vectors
– Eigendecomposition
– Singular value decomposition
– The Moore Penrose pseudoinverse
– The trace operator
– The determinant
– Ex: principal components analysis
Scalar

• **Single number**
  – In contrast to other objects in linear algebra, which are usually arrays of numbers

• **Represented in lower-case italic** $x$
  – They can be real-valued or be integers
  • E.g., let $x \in \mathbb{R}$ be the slope of the line
    – Defining a real-valued scalar
  • E.g., let $n \in \mathbb{N}$ be the number of units
    – Defining a natural number scalar
Vector

- An array of numbers arranged in order
- Each no. identified by an index
- Written in lower-case bold such as \( \mathbf{x} \)
  - its elements are in italics lower case, subscripted
    
\[
\mathbf{x} = \begin{bmatrix}
x_1 \\
x_2 \\
x_n 
\end{bmatrix}
\]

- If each element is in \( \mathbb{R} \) then \( \mathbf{x} \) is in \( \mathbb{R}^n \)
- We can think of vectors as points in space
  - Each element gives coordinate along an axis
Matrices

• 2-D array of numbers
  – So each element identified by two indices

• Denoted by bold typeface $\mathbf{A}$
  – Elements indicated by name in italic but not bold
    • $A_{1,1}$ is the top left entry and $A_{m,n}$ is the bottom right entry
    • We can identify nos in vertical column $j$ by writing : for the horizontal coordinate
      • E.g.,
        $$\mathbf{A} = \begin{bmatrix}
        A_{1,1} & A_{1,2} \\
        A_{2,1} & A_{2,2}
        \end{bmatrix}$$
    • $A_{i,:}$ is $i^{\text{th}}$ row of $\mathbf{A}$, $A_{:,j}$ is $j^{\text{th}}$ column of $\mathbf{A}$

• If $\mathbf{A}$ has shape of height $m$ and width $n$ with real-values then $\mathbf{A} \in \mathbb{R}^{m \times n}$
Tensor

• Sometimes need an array with more than two axes
  – E.g., an RGB color image has three axes
• A tensor is an array of numbers arranged on a regular grid with variable number of axes
  – See figure next
• Denote a tensor with this bold typeface: $\mathbf{A}$
• Element $(i,j,k)$ of tensor denoted by $A_{i,j,k}$
Shapes of Tensors

1d-tensor

2d-tensor

3d-tensor

4d-tensor

5d-tensor

6d-tensor
Transpose of a Matrix

• An important operation on matrices
• The transpose of a matrix $A$ is denoted as $A^T$
• Defined as

$$(A^T)_{i,j} = A_{j,i}$$

– The mirror image across a diagonal line

• Called the main diagonal, running down to the right starting from upper left corner

$$A = \begin{bmatrix} A_{1,1} & A_{1,2} & A_{1,3} \\ A_{2,1} & A_{2,2} & A_{2,3} \\ A_{3,1} & A_{3,2} & A_{3,3} \end{bmatrix} \Rightarrow A^T = \begin{bmatrix} A_{1,1} & A_{2,1} & A_{3,1} \\ A_{1,2} & A_{2,2} & A_{3,2} \\ A_{1,3} & A_{2,3} & A_{3,3} \end{bmatrix}$$
Vectors as special case of matrix

- Vectors are matrices with a single column
- Often written in-line using transpose

\[ \mathbf{x} = [x_1, \ldots, x_n]^T \]

\[ \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix} \Rightarrow \mathbf{x}^T = [x_1, x_2, \ldots, x_n] \]

- A scalar is a matrix with one element

\[ a = a^T \]
Matrix Addition

- We can add matrices to each other if they have the same shape, by adding corresponding elements
  - If $A$ and $B$ have same shape (height $m$, width $n$)
    \[ C = A + B \Rightarrow C_{i,j} = A_{i,j} + B_{i,j} \]

- A scalar can be added to a matrix or multiplied by a scalar
  \[ D = aB + c \Rightarrow D_{i,j} = aB_{i,j} + c \]

- Less conventional notation used in ML:
  - Vector added to matrix
    \[ C = A + b \Rightarrow C_{i,j} = A_{i,j} + b_j \]
      - Called broadcasting since vector $b$ added to each row of $A$
Multiplying Matrices

• For product \( C = AB \) to be defined, \( A \) has to have the same no. of columns as the no. of rows of \( B \)
  – If \( A \) is of shape \( m \times n \) and \( B \) is of shape \( n \times p \) then matrix product \( C \) is of shape \( m \times p \)

\[
C = AB \Rightarrow C_{i,j} = \sum_k A_{i,k} B_{k,j}
\]

– Note that the standard product of two matrices is not just the product of two individual elements
  • Such a product does exist and is called the element-wise product or the Hadamard product \( A \oslash B \)
Multiplying Vectors

• Dot product between two vectors $\mathbf{x}$ and $\mathbf{y}$ of same dimensionality is the matrix product $\mathbf{x}^T \mathbf{y}$

• We can think of matrix product $C = AB$ as computing $C_{ij}$ the dot product of row $i$ of $A$ and column $j$ of $B$
Matrix Product Properties

- Distributivity over addition: \( A(B + C) = AB + AC \)
- Associativity: \( A(BC) = (AB)C \)
- Not commutative: \( AB \neq BA \) is not always true
- Dot product between vectors is commutative: \( x^T y = y^T x \)
- Transpose of a matrix product has a simple form: \( (AB)^T = B^T A^T \)
Example flow of tensors in ML

A linear classifier

\[ y = Wx^T + b \]

Vector \( x \) is converted into vector \( y \) by multiplying \( x \) by a matrix \( W \)

A linear classifier with bias eliminated

\[ y = Wx^T \]
**Linear Transformation**

- \( Ax = b \)
  - where \( A \in \mathbb{R}^{n \times n} \) and \( b \in \mathbb{R}^n \)
  - More explicitly:
    \[
    A_{11}x_1 + A_{12}x_2 + \ldots + A_{1n}x_n = b_1 \\
    A_{21}x_1 + A_{22}x_2 + \ldots + A_{2n}x_n = b_2 \\
    \vdots \\
    A_{n1}x_1 + A_{n2}x_2 + \ldots + A_{nn}x_n = b_n
    \]
  - \( n \) equations in \( n \) unknowns

\[
A = \begin{bmatrix}
  A_{11} & \cdots & A_{1n} \\
  \vdots & \ddots & \vdots \\
  A_{n1} & \cdots & A_{nn}
\end{bmatrix}, \quad x = \begin{bmatrix}
  x_1 \\
  \vdots \\
  x_n
\end{bmatrix}, \quad b = \begin{bmatrix}
  b_1 \\
  \vdots \\
  b_n
\end{bmatrix}
\]

Can view \( A \) as a *linear transformation* of vector \( x \) to vector \( b \)

- Sometimes we wish to solve for the unknowns \( \mathbf{x} = \{x_1, \ldots, x_n\} \) when \( A \) and \( b \) provide constraints
Identity and Inverse Matrices

• Matrix inversion is a powerful tool to analytically solve $A x = b$
• Needs concept of Identity matrix
• Identity matrix does not change value of vector when we multiply the vector by identity matrix
  – Denote identity matrix that preserves n-dimensional vectors as $I_n$
  – Formally $I_n \in \mathbb{R}^{n \times n}$ and $\forall x \in \mathbb{R}^n, I_n x = x$
  – Example of $I_3$

\[
\begin{bmatrix}
1 & 0 & 0 \\
0 & 1 & 0 \\
0 & 0 & 1
\end{bmatrix}
\]
Matrix Inverse

- Inverse of square matrix $A$ defined as $A^{-1}A = I_n$

- We can now solve $Ax = b$ as follows:
  
  $Ax = b$
  $A^{-1}Ax = A^{-1}b$
  $I_n x = A^{-1}b$
  $x = A^{-1}b$

- This depends on being able to find $A^{-1}$

- If $A^{-1}$ exists there are several methods for finding it
Solving Simultaneous equations

- \( A x = b \)

where \( A \) is \((M+1) \times (M+1)\)

\( x \) is \((M+1) \times 1\): set of weights to be determined

\( b \) is \(N \times 1\)
Example: System of Linear Equations in Linear Regression

• Instead of $Ax = b$
• We have $\Phi w = t$
  – where $\Phi$ is $m \times n$ design matrix of $m$ features for $n$ samples $x_j, j=1,..n$
  – $w$ is weight vector of $m$ values
  – $t$ is target values of sample, $t = [t_1,..t_n]$
  – We need weight $w$ to be used with $m$ features to determine output

$$y(x,w) = \sum_{i=1}^{m} w_i x_i$$
Closed-form solutions

- Two closed-form solutions
  1. Matrix inversion \( x = A^{-1} b \)
  2. Gaussian elimination
Linear Equations: Closed-Form Solutions

1. Matrix Formulation: $Ax = b$
Solution: $x = A^{-1}b$

\[ a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n = b_1 \\
\vdots \\
a_{m1}x_1 + a_{m2}x_2 + \cdots + a_{mn}x_n = b_m \]

\[ A = \begin{bmatrix}
    a_{11} & a_{12} & \cdots & a_{1n} \\
a_{21} & a_{22} & \cdots & a_{2n} \\
    \vdots & \vdots & \ddots & \vdots \\
a_{m1} & a_{m2} & \cdots & a_{mn}
\end{bmatrix}, \quad \mathbf{x} = \begin{bmatrix}
    x_1 \\
x_2 \\
    \vdots \\
x_n
\end{bmatrix}, \quad \mathbf{b} = \begin{bmatrix}
    b_1 \\
b_2 \\
    \vdots \\
b_m
\end{bmatrix} \]

2. Gaussian Elimination followed by back-substitution

\[
\begin{align*}
    \begin{bmatrix}
        1 & 3 & -2 & 5 \\
        3 & 5 & 6 & 7 \\
        2 & 4 & 3 & 8
    \end{bmatrix} & \rightarrow \begin{bmatrix}
        1 & 3 & -2 & 5 \\
        0 & -4 & 12 & -8 \\
        0 & -2 & 7 & -2
    \end{bmatrix} \\
    & \rightarrow \begin{bmatrix}
        1 & 3 & -2 & 5 \\
        0 & 1 & -3 & 2 \\
        0 & 0 & 1 & 2
    \end{bmatrix} \\
& \rightarrow \begin{bmatrix}
        1 & 0 & 0 & -15 \\
        0 & 1 & 0 & 8 \\
        0 & 0 & 1 & 2
    \end{bmatrix}
\end{align*}
\]

\[
\begin{align*}
    \begin{bmatrix}
        1 & 3 & -2 & 5 \\
        3 & 5 & 6 & 7 \\
        2 & 4 & 3 & 8
    \end{bmatrix} & \rightarrow \begin{bmatrix}
        1 & 3 & -2 & 5 \\
        0 & -4 & 12 & -8 \\
        0 & -2 & 7 & -2
    \end{bmatrix} \\
& \rightarrow \begin{bmatrix}
        1 & 3 & -2 & 5 \\
        0 & 1 & -3 & 2 \\
        0 & 0 & 1 & 2
    \end{bmatrix} \\
& \rightarrow \begin{bmatrix}
        1 & 0 & 0 & -15 \\
        0 & 1 & 0 & 8 \\
        0 & 0 & 1 & 2
    \end{bmatrix}
\end{align*}
\]
Disadvantage of closed-form solutions

- If $A^{-1}$ exists, the same $A^{-1}$ can be used for any given $b$
  - But $A^{-1}$ cannot be represented with sufficient precision
  - It is not used in practice
- Gaussian elimination also has disadvantages
  - numerical instability (division by small no.)
  - $O(n^3)$ for $n \times n$ matrix
- Software solutions use value of $b$ in finding $x$
  - E.g., difference (derivative) between $b$ and output is used iteratively
How many solutions for $Ax = b$ exist?

- System of equations with $n$ variables and $m$ equations is:
  
  Solution is $x = A^{-1}b$

- In order for $A^{-1}$ to exist $Ax = b$ must have **exactly** one solution for every value of $b$

  - It is also possible for the system of equations to have *no solutions* or an *infinite no. of solutions* for some values of $b$

  - It is not possible to have more than one but fewer than infinitely many solutions

  - If $x$ and $y$ are solutions then $z = \alpha x + (1-\alpha) y$ is a solution for any real $\alpha$
Span of a set of vectors

- Span of a set of vectors: set of points obtained by a *linear combination* of those vectors
- A linear combination of vectors \( \{v^{(1)}, \ldots, v^{(n)}\} \) with coefficients \( c_i \) is \( \sum_i c_i v^{(i)} \)
- System of equations is \( Ax = b \)
  - A column of \( A \), i.e., \( A_{:,i} \) specifies travel in direction \( i \)
  - How much we need to travel is given by \( x_i \)
  - This is a linear combination of vectors
- Thus determining whether \( Ax = b \) has a solution is equivalent to determining whether \( b \) is in the span of columns of \( A \)
  - This span is referred to as *column space* or *range* of \( A \)
Conditions for a solution to $Ax = b$

- Matrix must be square, i.e., $m=n$ and all columns must be linearly independent
  - Necessary condition is $n \geq m$
    - For a solution to exist when $A \in \mathbb{R}^{m \times n}$ we require the column space be all of $\mathbb{R}^m$
  - Sufficient Condition
    - If columns are linear combinations of other columns, column space is less than $\mathbb{R}^m$
      - Columns are linearly dependent or matrix is singular
    - For column space to encompass $\mathbb{R}^m$ at least one set of $m$ linearly independent columns

- For non-square and singular matrices
  - Methods other than matrix inversion are used
Use of a Vector in Regression

- A design matrix
  - N samples, D features

- Feature vector has three dimensions
- This is a regression problem
Norms

• Used for measuring the size of a vector
• Norms map vectors to non-negative values
• Norm of vector $\mathbf{x} = [x_1, \ldots, x_n]^T$ is distance from origin to $\mathbf{x}$
  
  – It is any function $f$ that satisfies:

$$
\begin{align*}
  f(\mathbf{x}) = 0 & \Rightarrow \mathbf{x} = 0 \\
  f(\mathbf{x} + \mathbf{y}) & \leq f(\mathbf{x}) + f(\mathbf{y}) \quad \text{Triangle Inequality} \\
  \forall \alpha \in \mathbb{R} & \quad f(\alpha \mathbf{x}) = |\alpha| f(\mathbf{x})
\end{align*}
$$
**$L^P$ Norm**

- **Definition:**
  \[ \|x\|_p = \left( \sum_{i} |x_i|^p \right)^{1/p} \]

  - **$L^2$ Norm**
    - Called Euclidean norm
    - Simply the Euclidean distance between the origin and the point $x$
    - written simply as $\|x\|$
    - Squared Euclidean norm is same as $x^T x$

  - **$L^1$ Norm**
    - Useful when 0 and non-zero have to be distinguished
    - Note that $L^2$ increases slowly near origin, e.g., $0.1^2 = 0.01$

  - **$L^\infty$ Norm**
    \[ \|x\|_\infty = \max_i |x_i| \]

  - Called max norm
Use of norm in Regression

- Linear Regression
  - $\mathbf{x}$: a vector, $\mathbf{w}$: weight vector
  - $y(\mathbf{x}, \mathbf{w}) = w_0 + w_1 x_1 + \ldots + w_d x_d = \mathbf{w}^T \mathbf{x}$
  
  With nonlinear basis functions $\phi_j$
  - $y(\mathbf{x}, \mathbf{w}) = w_0 + \sum_{j=1}^{M-1} w_j \phi_j(\mathbf{x})$

- Loss Function
  - $\tilde{E}(\mathbf{w}) = \frac{1}{2} \sum_{n=1}^{N} \left\{ y(x_n, \mathbf{w}) - t_n \right\}^2 + \frac{\lambda}{2} \left\| \mathbf{w} \right\|^2$

Second term is a weighted norm called a regularizer (to prevent overfitting)
$L^P$ Norm and Distance

- Norm is the length of a vector

- We can use it to draw a unit circle from origin
  - Different $P$ values yield different shapes
    - Euclidean norm yields a circle

- Distance between two vectors $(\mathbf{v}, \mathbf{w})$
  - $\text{dist}(\mathbf{v}, \mathbf{w}) = ||\mathbf{v} - \mathbf{w}||$
  - $||\mathbf{v} - \mathbf{w}|| = \sqrt{(v_1 - w_1)^2 + \ldots + (v_n - w_n)^2}$
  - Distance to origin would just be sqrt of sum of squares
Size of a Matrix: Frobenius Norm

- Similar to $L^2$ norm

$$\|A\|_F = \left( \sum_{i,j} A_{i,j}^2 \right)^{1/2}$$

$$A = \begin{bmatrix} 2 & -1 & 5 \\ 0 & 2 & 1 \\ 3 & 1 & 1 \end{bmatrix}, \quad \|A\| = \sqrt{4 + 1 + 25 + \ldots + 1} = \sqrt{46}$$

- Frobenius in ML
  - Layers of neural network involve matrix multiplication
  - Regularization:
    - minimize Frobenius of weight matrices $\|W(i)\|$ over $L$ layers

$$J_R = J + \lambda \sum_{i=1}^{L} \|W^{(i)}\|_F$$

$$I_{1 \times (I+1)} \times V_{(I+1) \times J} = \text{net}_J$$

$$h_j = f(\text{net}_j), \quad f(x) = 1/(1+e^{-x})$$
Angle between Vectors

- Dot product of two vectors can be written in terms of their $L^2$ norms and angle $\theta$ between them:

$$x^T y \Rightarrow \|x\|_2 \|y\|_2 \cos \theta$$

- Cosine between two vectors is a measure of their similarity:

$$\text{similarity} = \cos(\theta) = \frac{\mathbf{A} \cdot \mathbf{B}}{||\mathbf{A}|| \||\mathbf{B}||} = \frac{\sum_{i=1}^{n} A_i B_i}{\sqrt{\sum_{i=1}^{n} A_i^2 \sqrt{\sum_{i=1}^{n} B_i^2}}}$$
Special kind of Matrix: Diagonal

- Diagonal Matrix has mostly zeros, with non-zero entries only in diagonal
  - E.g., identity matrix, where all diagonal entries are 1
    \[
    \begin{bmatrix}
      1 & 0 & 0 \\
      0 & 1 & 0 \\
      0 & 0 & 1
    \end{bmatrix}
    \]
  - E.g., covariance matrix with independent features

\[
\begin{align*}
Cov(X, Y) &= \sigma_{XY} = E[(X - \mu_X)(Y - \mu_Y)] \\
\text{Covariance} &= \sum_{i=1}^{n} (X_i - \bar{X})(Y_i - \bar{Y})/n - 1 \\
\text{Covariance} &= -64.57/8 = -8.07
\end{align*}
\]

If \( \text{Cov}(X, Y) = 0 \) then \( E(XY) = E(X)E(Y) \)

\[
N(x | \mu, \Sigma) = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp \left\{ -\frac{1}{2} (x - \mu)^T \Sigma^{-1} (x - \mu) \right\}
\]
Efficiency of Diagonal Matrix

- \text{diag}(\mathbf{v}) \text{ denotes a square diagonal matrix with diagonal elements given by entries of vector } \mathbf{v}.

- Multiplying vector \mathbf{x} by a diagonal matrix is efficient.
  - To compute \text{diag}(\mathbf{v})\mathbf{x} we only need to scale each \( x_i \) by \( v_i \):
    \[
    \text{diag}(\mathbf{v})\mathbf{x} = \mathbf{v} \odot \mathbf{x}
    \]

- Inverting a square diagonal matrix is efficient.
  - Inverse exists iff every diagonal entry is nonzero, in which case
    \[
    \text{diag}(\mathbf{v})^{-1} = \text{diag} \left( \left[ 1/v_1, \ldots, 1/v_n \right]^T \right)
    \]
Special kind of Matrix: Symmetric

- A symmetric matrix equals its transpose: $A = A^T$
  - E.g., a distance matrix is symmetric with $A_{ij} = A_{ji}$
  - E.g., covariance matrices are symmetric
Special Kinds of Vectors

• **Unit Vector**
  – A vector with unit norm
    \[ \|x\|_2 = 1 \]

• **Orthogonal Vectors**
  – A vector \( x \) and a vector \( y \) are orthogonal to each other if \( x^T y = 0 \)
    • If vectors have nonzero norm, vectors at 90 degrees to each other

– **Orthonormal Vectors**
  • Vectors are orthogonal & have unit norm
  • **Orthogonal Matrix**
    – A square matrix whose rows are mutually orthonormal:
      \[ A^T A = A A^T = I \]
      \[ A^{-1} = A^T \]
    Orthogonal matrices are of interest because their inverse is very cheap to compute
Matrix decomposition

- Matrices can be decomposed into factors to learn universal properties, just like integers:
  - Properties not discernible from their representation

1. Decomposition of integer into prime factors
   - From $12 = 2 \times 2 \times 3$ we can discern that
     - $12$ is not divisible by $5$ or
     - any multiple of $12$ is divisible by $3$
     - But representations of $12$ in binary or decimal are different

2. Decomposition of Matrix $A$ as $A = V \text{diag}(\lambda) V^{-1}$
   - where $V$ is formed of eigenvectors and $\lambda$ are eigenvalues, e.g,

\[
A = \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix} \quad \text{has eigenvalues } \lambda = 1 \text{ and } \lambda = 3 \text{ and eigenvectors } V: \\
\begin{bmatrix} v_{\lambda=1} = 1 \\ -1 \end{bmatrix}, v_{\lambda=3} = \begin{bmatrix} 1 \\ 1 \end{bmatrix}.
\]
Eigenvector

- An eigenvector of a square matrix $A$ is a non-zero vector $v$ such that multiplication by $A$ only changes the scale of $v$
  \[ A v = \lambda v \]
  - The scalar $\lambda$ is known as eigenvalue
- If $v$ is an eigenvector of $A$, so is any rescaled vector $sv$. Moreover $sv$ still has the same eigen value. Thus look for a unit eigenvector
Eigenvalue and Characteristic Polynomial

- Consider $A v = w$

- If $v$ and $w$ are scalar multiples, i.e., if $A v = \lambda v$
  - then $v$ is an eigenvector of the linear transformation $A$ and the scale factor $\lambda$ is the eigenvalue corresponding to the eigenvector

- This is the **eigenvalue equation** of matrix $A$
  - Stated equivalently as $(A - \lambda I)v = 0$
  - This has a non-zero solution if $|A - \lambda I| = 0$
    - The polynomial of degree $n$ can be factored as $|A - \lambda I| = (\lambda_1 - \lambda)(\lambda_2 - \lambda) \ldots (\lambda_n - \lambda)$
    - The $\lambda_1, \lambda_2 \ldots \lambda_n$ are roots of the polynomial and are eigenvalues of $A$
Example of Eigenvalue/Eigenvector

• Consider the matrix

\[ A = \begin{bmatrix} 2 & 1 \\ 1 & 2 \end{bmatrix} \]

• Taking determinant of \((A-\lambda I)\), the char poly is

\[ |A - \lambda I| = \begin{vmatrix} 2 - \lambda & 1 \\ 1 & 2 - \lambda \end{vmatrix} = 3 - 4\lambda + \lambda^2 \]

• It has roots \(\lambda = 1\) and \(\lambda = 3\) which are the two eigenvalues of \(A\)

• The eigenvectors are found by solving for \(v\) in \(A v = \lambda v\), which are

\[ v_{\lambda=1} = \begin{bmatrix} 1 \\ -1 \end{bmatrix}, v_{\lambda=3} = \begin{bmatrix} 1 \\ 1 \end{bmatrix} \]
Eigendecomposition

• Suppose that matrix $A$ has $n$ linearly independent eigenvectors $\{v^{(1)}, ..., v^{(n)}\}$ with eigenvalues $\{\lambda_1, ..., \lambda_n\}$

• Concatenate eigenvectors to form matrix $V$

• Concatenate eigenvalues to form vector $\lambda=[\lambda_1, ..., \lambda_n]$

• Eigendecomposition of $A$ is given by

$$A = V\text{diag}(\lambda) \ V^{-1}$$
Decomposition of Symmetric Matrix

• Every real symmetric matrix \( A \) can be decomposed into real-valued eigenvectors and eigenvalues

\[
A = Q \Lambda Q^T
\]

where \( Q \) is an orthogonal matrix composed of eigenvectors of \( A: \{v^{(1)}, \ldots, v^{(n)}\} \)

orthogonal matrix: components are orthogonal or \( v^{(i)^T}v^{(j)} = 0 \)

\( \Lambda \) is a diagonal matrix of eigenvalues \( \{\lambda_1, \ldots, \lambda_n\} \)

• We can think of \( A \) as scaling space by \( \lambda_i \) in direction \( v^{(i)} \)

–See figure on next slide
Effect of Eigenvectors and Eigenvalues

- Example of $2 \times 2$ matrix
- Matrix $A$ with two orthonormal eigenvectors
  - $v^{(1)}$ with eigenvalue $\lambda_1$, $v^{(2)}$ with eigenvalue $\lambda_2$

Plot of unit vectors $u \in \mathbb{R}^2$

Plot of vectors $Au$

with two variables $x_1$ and $x_2$
Python Code for Eigenvalue/Eigenvector

- https://www.youtube.com/watch?v=mxkGMbrobY0&feature=youtu.be&fbclid=IwAR3ajOaxWmnV-rYnAa6cwYfq9j6is6-H8UhnIMCkhBu3Cqfvby_vicyU2fg

```
import numpy as np
import matplotlib.pyplot as plt
from numpy import linalg

t = np.linspace(-4, 4, 100)
y = np.sqrt(1 - t**2)
plt.plot(t, y, 'r')
plt.plot(0, 0, 'r*', markersize=15)
plt.plot(-2, 2, 'b*')
plt.plot(2, 2, 'b*')
plt.plot(t, y, 'r--', lw=2)
plt.show()

def transformation(x, y):
    return 4*x - 4*y, 4*x + 3*y
	x_new1, y_new1 = transformation(x, y)
	x_new2, y_new2 = transformation(x, y)
plt.plot(x_new1, y_new1, 'k')
plt.plot(x_new2, y_new2, 'k')
eigenvals, eigvecs = np.linalg.eig(np.array([[9, 4], [4, 3]]))
print('Eigenvectors', eigvecs)
print('Eigenvalues', eigenvals)
```
Eigendecomposition is not unique

• Eigendecomposition is $A = Q \Lambda Q^T$
  – where $Q$ is an orthogonal matrix composed of eigenvectors of $A$

• Decomposition is not unique when two eigenvalues are the same

• By convention order entries of $\Lambda$ in descending order:
  – Under this convention, eigendecomposition is unique if all eigenvalues are unique
What does eigendecomposition tell us?

• Tells us useful facts about the matrix:
  1. Matrix is *singular* if & only if any eigenvalue is zero
  2. Useful to optimize quadratic expressions of form

\[ f(\mathbf{x}) = \mathbf{x}^T A \mathbf{x} \text{ subject to } \|\mathbf{x}\|_2 = 1 \]

Whenever \( \mathbf{x} \) is equal to an eigenvector, \( f \) is equal to the corresponding eigenvalue

Maximum value of \( f \) is max eigen value, minimum value is min eigen value

Example of such a quadratic form appears in multivariate Gaussian

\[
N(\mathbf{x} \mid \mu, \Sigma) = \frac{1}{(2\pi)^{D/2} |\Sigma|^{1/2}} \exp\left\{ -\frac{1}{2} (\mathbf{x} - \mu)^T \Sigma^{-1} (\mathbf{x} - \mu) \right\}
\]
Positive Definite Matrix

- A matrix whose eigenvalues are all positive is called *positive definite*
  - Positive or zero is called *positive semidefinite*
- If eigen values are all negative it is *negative definite*
  - Positive definite matrices guarantee that $x^T A x \geq 0$
Singular Value Decomposition (SVD)

- Eigendecomposition has form: \( A = V \text{diag}(\lambda) V^{-1} \)
  - If \( A \) is not square, eigendecomposition is undefined
- SVD is a decomposition of the form \( A = UDV^T \)
- SVD is more general than eigendecomposition
  - Used with any matrix rather than symmetric ones
  - Every real matrix has a SVD
    - Same is not true of eigen decomposition
SVD Definition

• Write $A$ as a product of 3 matrices: $A = UDV^T$
  – If $A$ is $m \times n$, then $U$ is $m \times m$, $D$ is $m \times n$, $V$ is $n \times n$

• Each of these matrices have a special structure
  • $U$ and $V$ are orthogonal matrices
  • $D$ is a diagonal matrix not necessarily square
    – Elements of Diagonal of $D$ are called singular values of $A$
    – Columns of $U$ are called left singular vectors
    – Columns of $V$ are called right singular vectors

• SVD interpreted in terms of eigendecomposition
  • Left singular vectors of $A$ are eigenvectors of $AA^T$
  • Right singular vectors of $A$ are eigenvectors of $A^TA$
  • Nonzero singular values of $A$ are square roots of eigenvalues of $A^TA$. Same is true of $AA^T$
Use of SVD in ML

1. SVD is used in generalizing matrix inversion
   - Moore-Penrose inverse (discussed next)

2. Used in Recommendation systems
   - Collaborative filtering (CF)
     - Method to predict a rating for a user-item pair based on the history of ratings given by the user and given to the item
     - Most CF algorithms are based on user-item rating matrix where each row represents a user, each column an item
       - Entries of this matrix are ratings given by users to items
     - SVD reduces no. of features of a data set by reducing space dimensions from $N$ to $K$ where $K < N$
SVD in Collaborative Filtering

$$\hat{X} \approx U S V^T$$

- $X$ is the utility matrix
  - $X_{ij}$ denotes how user $i$ likes item $j$
  - CF fills blank (cell) in utility matrix that has no entry
- Scalability and sparsity is handled using SVD
  - SVD decreases dimension of utility matrix by extracting its latent factors
    - Map each user and item into latent space of dimension $r$
Moore-Penrose Pseudoinverse

• Most useful feature of SVD is that it can be used to generalize matrix inversion to non-square matrices

• Practical algorithms for computing the pseudoinverse of $A$ are based on SVD

\[ A^+ = VD^+ U^T \]

– where $U, D, V$ are the SVD of $A$

• Pseudoinverse $D^+$ of $D$ is obtained by taking the reciprocal of its nonzero elements when taking transpose of resulting matrix
Trace of a Matrix

- Trace operator gives the sum of the elements along the diagonal
  \[ \text{Tr}(A) = \sum_{i,i} A_{i,i} \]

- Frobenius norm of a matrix can be represented as
  \[ \|A\|_F = \left( \text{Tr}(A) \right)^{\frac{1}{2}} \]
Determinant of a Matrix

• Determinant of a square matrix $\det(A)$ is a mapping to a scalar
• It is equal to the product of all eigenvalues of the matrix
• Measures how much multiplication by the matrix expands or contracts space
Example: PCA

• A simple ML algorithm is *Principal Components Analysis*

• It can be derived using only knowledge of basic linear algebra
PCA Problem Statement

- Given a collection of $m$ points $\{x^{(1)}, \ldots, x^{(m)}\}$ in $\mathbb{R}^n$ represent them in a lower dimension.
  - For each point $x^{(i)}$ find a code vector $c^{(i)}$ in $\mathbb{R}^l$
  - If $l$ is smaller than $n$ it will take less memory to store the points
  - This is lossy compression
  - Find encoding function $f(x) = c$ and a decoding function $x \approx g(f(x))$
PCA using Matrix multiplication

• One choice of decoding function is to use matrix multiplication: \( g(c) = Dc \) where \( D \in \mathbb{R}^{n \times l} \)
  – \( D \) is a matrix with \( l \) columns

• To keep encoding easy, we require columns of \( D \) to be orthogonal to each other
  – To constrain solutions we require columns of \( D \) to have unit norm

• We need to find optimal code \( c^* \) given \( D \)

• Then we need optimal \( D \)
Finding optimal code given $D$

• To generate optimal code point $c^*$ given input $\mathbf{x}$, minimize the distance between input point $\mathbf{x}$ and its reconstruction $g(c^*)$

$$c^* = \underset{c}{\text{arg min}} \| \mathbf{x} - g(c) \|_2$$

– Using squared $L^2$ instead of $L^2$, function being minimized is equivalent to

$$(\mathbf{x} - g(c))^T (\mathbf{x} - g(c))$$

• Using $g(c) = Dc$ optimal code can be shown to be equivalent to

$$c^* = \underset{c}{\text{arg min}} - 2\mathbf{x}^T Dc + c^T c$$
Optimal Encoding for PCA

- Using vector calculus
  \[ \nabla_c (-2x^T Dc + c^T c) = 0 \]
  \[ -2D^Tx + 2c = 0 \]
  \[ c = D^Tx \]

- Thus we can encode \( x \) using a matrix-vector operation
  - To encode we use \( f(x) = D^Tx \)
  - For PCA reconstruction, since \( g(c) = Dc \) we use
    \[ r(x) = g(f(x)) = DD^Tx \]
  - Next we need to choose the encoding matrix \( D \)
Method for finding optimal $D$

- Revisit idea of minimizing $L^2$ distance between inputs and reconstructions
  - But cannot consider points in isolation
  - So minimize error over all points: Frobenius norm

$$D^* = \arg\min_D \left( \sum_{i,j} \left( x_j^{(i)} - r(x^{(i)})_j \right)^2 \right)^{1/2}$$

- subject to $D^T D = I_l$

- Use design matrix $X$, $X \in \mathbb{R}^{m \times n}$
  - Given by stacking all vectors describing the points

- To derive algorithm for finding $D^*$ start by considering the case $l = 1$
  - In this case $D$ is just a single vector $d$
Final Solution to PCA

• For \( l = 1 \), the optimization problem is solved using eigendecomposition
  – Specifically the optimal \( d \) is given by the eigenvector of \( X^T X \) corresponding to the largest eigenvalue

• More generally, matrix \( D \) is given by the \( l \) eigenvectors of \( X \) corresponding to the largest eigenvalues (Proof by induction)
