Generative Adversarial Networks: Theory

Sargur N. Srihari
srihari@cedar.buffalo.edu
Topics in GAN

1. **GAN Motivation**

2. **GAN Theory**
   1. Generator and Discriminator
   2. Adversarial Modeling framework
   3. GAN Objective and SGD
   4. Theoretical Results
   5. GAN Difficulties

3. **Mode Collapse**

4. **Wasserstein GAN**

5. **GAN Applications**
Generator Network

- To learn the generator’s distribution $p_g$ over data $x$, we define a prior on input noise variables $p_z(z)$
- Represent a mapping to data space as $G(z; \theta_g)$
  - where $G$ is a differentiable generator function represented by a multilayer perceptron with parameters $\theta_g$

$p(x,z) = p(x|z)p(z)$

$G(z)$ maps $z$ to $x$ which is distributed according to $p_g = p(x|z)$
Differentiable Generator Functions

1. To sample from \( x \sim \mathcal{N}(\mu, \Sigma) \):
   \[
x = g(z) = \mu + Lz
   \]
   - where \( L \) is the Cholesky decomposition of \( \Sigma \)
     - Decomposition: \( \Sigma = LL^T \) where \( L \) is lower triangular

2. To sample from any \( p(x) \)
   \[
z \sim \mathcal{U}(0, I) \quad \rightarrow \quad g(z) \quad \rightarrow \quad x \sim p(x)
   \]
   - Distribution is governed by
   \[
   p_x(x) = \frac{p_z(g^{-1}(x))}{\text{det}(\frac{\partial g}{\partial z})}
   \]
   - Denominator is determinant of Jacobian
   - Alternatively, define \( p(x|z) \) and marginalize \( z \):
     e.g., by using a VAE
Generator and Discriminator Networks

1. **Generator Network** produces samples

\[ x = G(z; \theta^{(g)}) \]

2. **Discriminator Network**

1. Attempts to distinguish samples drawn from training data and samples drawn from generator

2. Emits a probability value

\[ D(x; \theta^{(d)}) \]

indicating the probability that \( x \) is a real training example rather than a fake sample drawn from the model
Adversarial Modeling Framework

• We also define a second multilayer perceptron $D(x; \theta_d)$ that outputs a single scalar
  
  - $D(x)$ represents the probability that $x$ came from the data rather than $p_g$
Training of $D$ and $G$

1. We train $D$ to maximize the probability of assigning the correct label to both training examples and samples from $G$.

2. We simultaneously train $G$ to minimize $\log(1 - D(G(z)))$.

In other words, $D$ and $G$ play a two-player minimax game with Value Function $V(G,D)$.

$$\min_G \max_D V(D,G) = \mathbb{E}_{x \sim p_{\text{data}}}(x)[\log D(x)] + \mathbb{E}_{z \sim p_z}(z)[\log(1 - D(G(z)))]$$
Minimax value explanation

1. \( D \) is accurate over real data by maximizing

\[
\mathbb{E}_{x \sim p_{\text{data}}(x)}[\log D(x)]
\]

- Given sample \( G(z), z \sim p_z(z) \), \( D(G(z)) \) is close to zero by maximizing

\[
\mathbb{E}_{z \sim p(z)}[\log(1 - D(G(z)))]
\]

2. \( G \) is trained to increase \( D \)'s probability for a fake example,

- i.e. minimize

\[
\mathbb{E}_{z \sim p(z)}[\log(1 - D(G(z)))]
\]

- Combined together \( D \) and \( G \) are playing a minimax game in which we optimize:

\[
\min_D \max_G V(D, G) = \mathbb{E}_{x \sim p_{\text{data}}(x)}[\log D(x)] + \mathbb{E}_{z \sim p_z(z)}[\log(1 - D(G(z)))]
\]
Optimal value of $D$

- To find best value for $D$ consider

$$L(G,D) = \int_x (p_{data}(x) \log D(x) + p_g(x) \log(1 - D(x))) \, dx$$

- Since we want value of $D(x)$ to maximize $L(G,D)$, label $\tilde{x} = D(x)$, $A = p_{data}(x)$, $B = p_g(x)$

- What is inside integral is:

\[ f(x) = A \log x + B \log(1 - x) \]

\[ \frac{df(x)}{dx} = \frac{A}{\ln 10} \frac{1}{x - \frac{B}{\ln 10} \frac{1}{1 - x}} \]

\[ = \frac{1}{\ln 10} \left( \frac{A}{x - 1 - x} \right) \]

\[ = \frac{1}{\ln 10} \left( \frac{A}{1 - x} \right) \]

\[ = \frac{1}{\ln 10} \left( \frac{A}{x} \right) \]

\[ = \frac{1}{\ln 10} \left( \frac{A - (A + B)x}{x(1 - x)} \right) \]

- Setting the derivative to zero:

$$D^*(x) = x^* = \frac{A}{A + B} = \frac{p_r(x)}{p_r(x) + p_g(x)} \in [0, 1]$$

- Once $G$ is trained to optimal, $p_g$ is very close to $p_{data}$

- When $p_g = p_{data}$, $D^*(x)$ becomes $1/2$
Intuition in training of GAN

**Goal:**
Make these two equal

**Note:**
Here $p_g(G)$ is close to $p_{data}(x)$

- **Data generating distribution** $p_{data}(x)$
- **Generative distribution** $p_g(G(z))$

- **Discriminative distribution** $D$

- **Domain from which $z$ is sampled (uniformly)**

- **Non-uniform mapping** $x = G(z)$

$G$ contracts in regions of high density of $p_g(G)$ and expands in regions of low density
Deep Learning

Update of $D$

Data generating distribution $p_{data}(\mathbf{x})$

Generative distribution $p_g(G(z))$

Discriminative distribution $D(x)$

$x$

$z$

$D$ is trained to discriminate samples from data,

converging to

$$D^*(\mathbf{x}) = \frac{p_{data}(\mathbf{x})}{p_{data}(\mathbf{x}) + p_g(\mathbf{x})}$$
After an update to \( G \), gradient of \( D \) has guided \( G(z) \) to flow to regions that are more likely to be classified as data.
After several steps of training, if $D$ and $G$ have enough capacity, they will reach a point at which both cannot improve because $p_g = p_{data}$.

The discriminator is unable to differentiate between the two distributions, i.e., $D(x) = 0.5$. 
GAN Objective

- Value Function of Minimax Game played by Generator and Discriminator

\[
\min_D \max_G E_{x \sim p_X} [\log D(x)] + E_{z \sim p_Z} [\log (1 - D(G(z)))]
\]

- We must implement the game using an iterative, numerical approach

\[p_X: \text{data distribution, represented by samples}\]
\[p_{G(z)}: \text{model distribution, } z \text{ modeled as Gaussian}\]

---

Optimizing \(D\) to completion in inner loop of training is computationally prohibitive and results in overfitting in finite data sets.

Instead we alternate between \(k\) steps of optimizing \(D\) and one step of optimizing \(G\).
Interaction between $G$ and $D$

• **Weights are updated so as to**
  – maximize the probability that any real data input $x$ is classified as belonging to the real dataset, while
  – minimizing the probability that any fake image is classified as belonging to the real dataset

• **In more technical terms,**
  – Loss function maximizes the function $D(x)$, and it also minimizes $D(G(z))$
Alternating gradient updates

\[
\min_G \max_D E_{x \sim p_X} [\log D(x)] + E_{z \sim p_Z} [\log (1 - D(G(z)))]
\]

- **Step 1**: Fix \( G \) and perform a gradient step for maximization:
  \[
  \max_D E_{x \sim p_X} [\log D(x)] + E_{z \sim p_Z} [\log (1 - D(G(z)))]
  \]

- **Step 2**: Fix \( D \) and perform a gradient step for minimization:
  
  - In theory
    \[
    \min_G E_{z \sim p_Z} [\log (1 - D(G(z)))]
    \]
  
  - In practice
    \[
    \max_G E_{z \sim p_Z} [\log D(G(z))]
    \]
GAN Architecture

$G$ and $D$ are deep neural networks
Fine tune training consists of backpropagation
SGD for GAN

**Algorithm 1** Minibatch stochastic gradient descent training of generative adversarial nets. The number of steps to apply to the discriminator, $k$, is a hyperparameter. We used $k = 1$, the least expensive option, in our experiments.

1. **for** number of training iterations **do**
   1. **for** $k$ steps **do**
      1. Sample minibatch of $m$ noise samples $\{z^{(1)}, \ldots, z^{(m)}\}$ from noise prior $p_g(z)$.
      2. Sample minibatch of $m$ examples $\{x^{(1)}, \ldots, x^{(m)}\}$ from data generating distribution $p_{data}(x)$.
      3. Update the discriminator by ascending its stochastic gradient:
         $$\nabla_{\theta_d} \frac{1}{m} \sum_{i=1}^{m} \left[ \log D(x^{(i)}) + \log \left(1 - D\left(G\left(z^{(i)}\right)\right)\right) \right].$$
   2. **end for**
   3. Sample minibatch of $m$ noise samples $\{z^{(1)}, \ldots, z^{(m)}\}$ from noise prior $p_g(z)$.
   4. Update the generator by descending its stochastic gradient:
      $$\nabla_{\theta_g} \frac{1}{m} \sum_{i=1}^{m} \log \left(1 - D\left(G\left(z^{(i)}\right)\right)\right).$$
4. **end for**

The gradient-based updates can use any standard gradient-based learning rule. We used momentum in our experiments.
Theoretical Results

• **Theorem 1:**
  – The global minimum of the virtual training criterion
    \[ C(G) = \max_D V(G, D) \]
    is achieved iff \( p_g = p_{data} \)
  – At that point \( C(G) \) achieves the value \(-\log 4\)

• **Convergence of Algorithm 1:**
  – If \( G \) and \( D \) have enough capacity, and at each step of Algorithm 1, \( D \) is allowed to reach its optimum given \( G \), and \( p_g \) is updated so to improve the criterion
    \[
    = \mathbb{E}_{x \sim p_{data}(x)}[\log D(x)] + \mathbb{E}_{z \sim p_z(z)}[\log(1 - D(G(z)))]
    \]
  – Then \( p_g \) converges to \( p_{data} \)
GAN and Convexity

- Main motivation for GAN is that it requires neither approximate inference or approximation of partition function

- When $\max_d v(g, d)$ is convex in $\theta_g$
  - (such as optimization directly in the space of probability density functions)
  - the procedure is guaranteed to converge

- When $g$ and $d$ are neural nets and $\max_d v(g, d)$ is nonconvex
  - Learning is difficult
GAN underfit: nonconvergence

- Simultaneous gradient descent on two player’s costs is not guaranteed to reach an equilibrium

**Ex:** $v(a, b) = ab$

- where Player 1 controls $a$ and incurs cost $ab$, while Player 2 controls $b$ and receives cost $-ab$

- If each player makes small gradient steps, each player reducing own cost at expense of other,
  - then $a$ and $b$ go into a stable circular orbit, rather than arriving at the equilibrium point at the origin
Proposed Solutions

1. Game is no longer zero-sum
   – Same expected gradient as maximum likelihood learning
   – Does not work well in practice

2. $G$ increases probability that $D$ makes a mistake rather than aiming to decrease probability that $D$ makes right prediction
   – Motivated by keeping derivatives large

• Stabilization of GAN learning an open problem
Underfit and Overfit

- **Overfitting**
  - training loss $<<$ validation loss

- **Underfitting**
  - training loss $>>$ validation loss

- **Just right**
  - training loss $\approx$ validation loss
