Development of Individuality in Children's Handwriting

ABSTRACT: Handwriting of children in early grades is studied from the viewpoint of quantitatively measuring the development of handwriting individuality. Handwriting samples of children, in grades 2–4, writing a paragraph of text in both handprinted and cursive, collected over a period of 3 years, were analyzed using two different approaches: (i) characteristics of the word “and” and (ii) entire paragraphs using an automated system. In the first approach, word characteristics were analyzed using statistical measures. In the second approach, pairs of paragraphs were compared. Both types of analysis, single word and complete writing, led to the same conclusions: (i) handwriting of each child remains relatively similar when handwriting has been just learnt and becomes markedly different from grades 3 to 4 and (ii) handwriting of different children becomes progressively more different from grades 2 to 4. The results provide strong support that handwriting becomes more individualistic with child development.

KEYWORDS: forensic science, handwriting, forensics, individuality, statistics, child development

Forensic handwriting identification rests on the identifiability premises: No two individuals have been shown to share the same combination of individualizing characteristics, and no one person writes the same way twice due to natural variation (1–3). Statistical support for identifiability has been developed in the past using two types of data: (i) random samples from a population representative of the United States (4) and (ii) samples from twins to take the genetic factor into account (5).

Both previous approaches have a bias which we attempt to address in the study reported here. General population across the United States consists of people from different school systems or even different cultures. Therefore, they may learn how to write by different ways of teaching, or they may just learn to write in different writing systems. So, there is a large variation between their handwritings. Similarly, as for twin population, it is difficult to collect enough number of pairs of the twins in the same age range. So, a dataset of twins has wide variation in age. This study takes a third approach using samples from the population, who are in the same age and taught in the same way.

This study focuses on analysis over time, specifically children's handwriting as they develop their writing skills during early grades. Because the task of writer identification is based on the assumption of individuality of handwriting, it is important to be aware of how individual handwriting characteristics develop, given that students are taught to write in the same way beginning in primary school. Students are taught handprinting in kindergarten and cursive writing in second grade in a particular style, known as a writing system, for example, D'Nealian and

Zaner-Bloser. by copying letter and number formations from a copy book or from an instructional banner posted in their classroom. The writing system determines the *class characteristics* (properties common to a group) of all the students. Over time, with continued instruction and practice, each student's writing skills increase as well their confidence; they will stop copying the letters and numbers and instead will begin writing from memory. It is at this point that students are believed to begin developing their *individual characteristics* (unique to individual) (6).

This research uses extended handprinted and cursive writing samples from the same students over a 3-year span. The students, who attended four schools in the same school district in Minnesota, were instructed using the Zaner-Bloser system. An example of the writing is shown in Fig. 1.

The first year writings were collected from students attending grades 2–4 (school year 2011–12), the second year, from the same students, attending grades 3–5 (2012–2013) and the third year, while attending grades 4–6 (2013–2014). Questions this project aims to answer are as follows: (i) at what ages do individual handwriting characteristics begin to develop; (ii) at what rate do these individual handwriting characteristics develop; (iii) what are the most common (less unique) individual characteristics that develop, and (iv) what are the least common individual (more unique) individual characteristics that develop.

We took two different approaches in analyzing the handwriting samples. In the first approach, the distribution of the characteristics of a single word *and* was studied. The word, which was written multiple times, was extracted from all the writing samples, and the samples were assigned characteristic values by human FDEs using a truthing tool. The resulting data were analyzed first by constructing probabilistic graphical models (7), from which information theoretic measures were computed to determine the range of variations (8,9). In the second, the entire sample of writing, rather than a single word, was examined by

the use of an automated system for handwriting comparison, known as CEDAR-FOX (5).

Approach 1

The students wrote a paragraph four times each year; twice in cursive writing and twice handprinted. The paragraph consisted of the following text, consisting of seven sentences: *The brown fox went into the barn where he saw the black dog. After a second, the black dog saw the fox too. The brown fox was fast and quick. The black dog was not fast and he lost the fox. The fox hid in a hole and waited for the black dog to go home. After the black dog went home, the fox was able to go to the hole he called home and saw all the other foxes. The other foxes were glad to see him and they all asked him to tell them about his day.*

All the writing samples were collected using the same forms to control variation due to document size and/or format. All students received the same instructions, as each of the teachers read the same instruction paragraph prior to collecting the writing samples. This process was repeated each year.

The word *and* appears five times in the paragraph. This data-gathering process produced an average of 5–10 samples of the word per student in handprinted and in cursive (except for second graders) to be analyzed using a truthing tool, which assigns numbers to the subcategories involved with the 12 individual handwriting characteristics (7). The word *and* is one of few words that children write over and over during their early writings and have therefore begun to develop individual handwriting characteristics rather than words that are not written often.

Handwriting Characteristics

FDEs assign different characteristics to handwriting manually, depending on whether the writing is cursive or handprinted. The Zaner-Bloser Copy Book Handwriting Style (10), (see Fig. 2), is the handprinting/handwriting copy book style being taught in elementary schools in Minnesota to introduce children to writing. A handwritten letter, or a combination of letters such as the word *and*, can be represented by a set of D characteristics, $\mathbf{X} = \{X_i\}$, $i = 1, \dots, D$ where characteristic X_i takes one of d_i discrete values. The characteristics assigned to our dataset of children's handwriting are represented in Fig. 3.

Samples of handwritten *and* by children of grade 2, 3, and 4 and their respective feature values are shown in Fig. 4.

Information Theoretic Measures

In studying the differences between populations of different grades, a statistical measure, *relative entropy* (*K–L divergence*), becomes useful. It measures the change in disorder between two populations. Given a vector \mathbf{x} of discrete characteristics, and distributions $p(\mathbf{x})$ and $q(\mathbf{x})$, relative entropy is represented as:

$$KL(p||q) = \sum_{\mathbf{x}} p(\mathbf{x})(\ln p(\mathbf{x}) - \ln q(\mathbf{x}))$$

where \ln represents natural logarithm and the summation is over all $\prod_{i=1}^D d_i$ values of \mathbf{x} , $KL(p||q)$ represents information lost in nats (or in bits if logarithm has base 2) when q is used to represent p .

As we do not have the distributions but have samples $\{\mathbf{x}_1, \dots, \mathbf{x}_N\}$, the sampling version of relative entropy is as follows:

$$KL(p||q) = \frac{1}{N} \sum_{i=1}^N (\ln p(\mathbf{x}_i) - \ln q(\mathbf{x}_i))$$

The sampling version still needs distributions for computing K–L divergence. For this, we constructed Bayesian networks for each of the two distributions using a Bayesian network structure learning algorithm (9).

The relative entropies between different grades for handprinted and cursive handwriting datasets are shown in Table 1. Here, it is seen that the relative entropy between grade 2 (G_2) to grade 3 (G_3) is smaller than the relative entropy between grade 2 (G_2) and grade 4 (G_4). This reflects the development of individuality as the grades progress.

Conclusion for Approach 1

The extent of change between grades is measured by relative entropy: The relative entropy of handprinted writing between grades 2 and 3 is smaller than the relative entropy between grades 3 and 4, and grades 2 and 4.

A somewhat similar effect is seen with the mean of each distribution: (i) The mean for handprinted writing is closer to the

	N ₄ ^c	40	59	50	114	263

ideal (Zaner-Bloser) in grade 3 compared to grade 2, but moves further away for grade 4. However, the mean for cursive writing is closer to the ideal (Zaner-Bloser) for grade 4 compared to grade 3—which may not be as significant as the increase in entropy.

Approach 2

The automated analysis setup is described by the flowchart in Fig. 5. This analysis focused on handprinted and cursive samples from children in grade 2 during 2011–2012, and from the same children in grades 3 and 4 in the years 2012–2013 and 2013–2014. Table 2 shows the number of samples used. The schools are coded as follows: A = Liberty Ridge, B = Middleton, C = Red Rock, and D = Wildwood. N_i^h and N_i^c are the numbers of handprinted and cursive writing samples in grade *i*.

Handwriting samples were scanned as grayscale images in PNG format. There are three types of noise: printed instructions at the top, black vertical line in the left most part, and the dashed lines and solid lines crossing the letters, whose presence can influence accuracy of automatic comparison. So preprocessing is needed before comparison as shown in Fig. 6(a), which is the resulting image of Fig. 1(a).

First, the source image was cropped to eliminate instructions and vertical lines. After converting the input to a black and white reversed binary image, dashed lines can be easily removed by comparing the length with a threshold. Because dashed lines are built up by small connected parts, they can be removed while preserving handwriting strokes. Solid lines are removed with the help of a mask to preserve the intersection parts between the lines and handwritings. After multiplied by a predetermined weaken rate, the binary image is compressed vertically to build a mask, in which the intersection parts are intensified. Then, the means of each row are deducted from the pixel values. Therefore, when the mask is stretched back to its original size, the intersection parts’ information can still be preserved. So, when the weakened binary image is multiplied by the mask, and converted to binary image again using a restoration threshold, the solid lines can be removed while keeping strokes integral.

This method can get good results if the images are scanned in upright direction. However, the lines in the scanned images are

FIG. 5—Automated comparison overview.

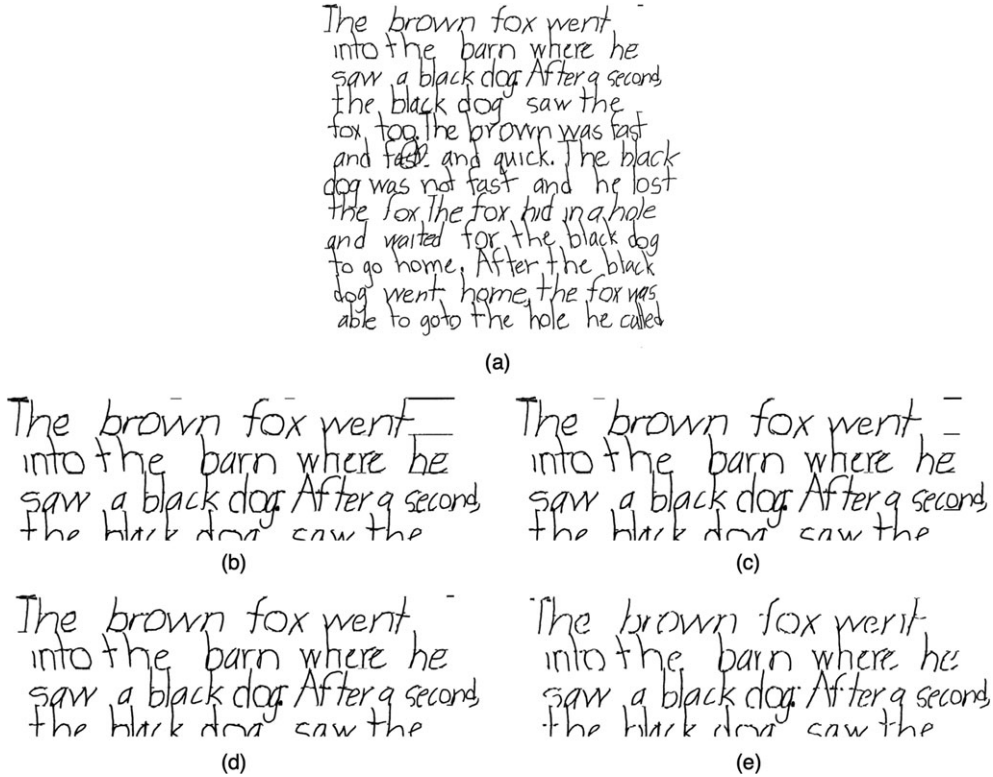

FIG. 6—Line removal with different parameter settings: (a) processed image, (b) #batch = 10, (c) #batch = 20, (d) #batch = 40, and (e) #batch = 80.

not perfectly horizontal, instead have a tiny slope. Thus, a line removal parameter, *number of batches*, is introduced. The column vectors of the binary image are first separated evenly into a certain number of batches, so that lines can be regarded as horizontal in each batch. Then, the batches are processed one by one to remove the lines (11).

The parameter, #batch, can influence the degree of line removal. Figure 6(b–e) illustrates the results with different values of #batch. With #batch = 10, some relatively long segments near the edge are not removed. With #batch = 20, there are only few noticeable line segments left. When #batch = 40, very few short lines can be found near the edge. With #batch = 80, solid lines and dash lines crossing the words are completely removed, but some other lines are removed incorrectly. This is because when batch number is small, we separate a relatively large number of columns into one batch, so we may mistakenly determine a short line as strokes. While when batch number is large, relatively small number of columns is assigned to one batch, so some long horizontal strokes, like the horizontal line of letter t, may be regarded as lines instead of strokes. It was concluded that removing less leads to segments still left. Removing too much leads to lines being removed incorrectly, for example, horizontal line of letter t, and continuous strokes becoming disconnected. So, we chose 20 or 40 for 8-bit images, and 10 for 16-bit images. Additionally, line removal was improved in the conversion to binary image part considering that the source images were in two formats: 8 bit and 16 bit.

Log-Likelihood Ratio Calculation

For performing comparisons of writing samples, we used the CEDAR-FOX software system (5). The indexed input images were first mapped with a transcript, containing the paragraph

which children were asked to copy. Then, based on the recognized characteristics, the system computes three types of features vectors, macrofeatures, microfeatures, and style features, to determine the strength of whether the two inputs are written by the same writer or not, which is measured by log-likelihood ratio (LLR). Examples of macrofeatures are grayscale entropy, slant, and height. Microfeatures represent handwriting characteristics such as stroke and structure, and style features come from pairs of letters, known as *bigrams*.

The dissimilarity of the two input images is measured by the distance between their feature vectors, which is computed by “Correlation” measure:

$$D(X, Y) = \frac{1}{2} - \frac{S_{11}S_{00} - S_{10}S_{01}}{2\sqrt{(S_{10} + S_{11})(S_{01} + S_{00})(S_{11} + S_{01})(S_{00} + S_{10})}}$$

where $S_{ij}(i, j \in \{0, 1\})$ represents the number of matches of i in vector X and j in Y . The distance data are represented by Gaussian and Gamma distributions, and parameters are estimated by maximum-likelihood estimation method and stored in the software system. Then, the likelihood of same writer L_s and the likelihood of different writer L_d can be expressed as:

$$L_s = \prod_{i=1}^c \prod_j \prod_k p_s(d_i(j, k))$$

$$L_d = \prod_{i=1}^c \prod_j \prod_k p_d(d_i(j, k))$$

where c is the number of writing elements, $d_i(j, k)$ is the distance between the j th element e_j appearing in the first document and

the k th e_i in the second, and p_s and p_d are the probability density functions of distances for same writer and different writer, respectively. Then, the log-likelihood ratio is given by the software as:

$$\text{LLR} = \sum_{i=1}^c \sum_j \sum_k [\ln p_s(d_i(j, k)) - \ln p_d(d_i(j, k))]$$

Therefore, a positive LLR means the likelihood ratio is larger than 1, so it is indicative of the same writer, while a negative LLR refers that the likelihood ratio is less than 1, which means the two inputs are from different writers. When LLR is close to zero, it means the answer is ambiguous (5).

Results

Two types of comparisons were made: (i) samples collected in two consecutive years by the same children and (ii) samples from different children in the same grade. The numbers of comparisons made were N_{ij}^h for handprinted samples and N_{ij}^c for cursive samples, where $N_{ij}^h = \min\{N_i^h, N_j^h\}$ and $N_{ij}^c = \min\{N_i^c, N_j^c\}$. A total of 2755 comparisons were made: 1974 of them for handprinted writing, and 781 for cursive writing. The mean and standard deviation of the computed LLRs are shown as Tables 3 and 4, where Table 3 is the results of comparing same child in different grades and Table 4 is for comparing different children in the same grade.

Figure 7 graphically illustrates the means and standard deviations for each comparison type: Means are represented as crosses and standard deviations as vertical lines. Figure 7(a) is from comparing the same children's handprinted writing in two consecutive years: The vertical lines are for comparisons between grade 2 and grade 3, grade 3 and grade 4, and grade 2 and grade 4. Figure 7(b) also refers to the comparisons between the same

G_i^d = Comparison of different children in grade i .

μ_i^h = Mean of LLR from comparing handprinted samples of grades i .

μ_i^c = Mean of LLR from comparing cursive samples of grades i .

σ_i^h = Std. deviation of LLR from comparing handprinted samples of grades i .

σ_i^c = Std. deviation of LLR from comparing cursive samples of grades i .

children but wrote in cursive style. Figure 7(c) and (d) illustrate the results for comparing two images from two different children in the same grade. For handprinted, results for grade 2, grade 3, and grade 4 are shown in Fig. 7(c). While for cursive, Fig. 7(d) shows the results from children in grade 3 and the results when they moved up to grade 4.

An example of handwriting for the same child MAA2022VA in different years is shown in Fig. 8: (a) is from grade 2 in 2011–2012, (b) is from the same child in grade 3 in 2012–2013, and (c) is from the third year. Comparing images from grades 2 and 3, LLR=51.71, and between grades 3 and 4, LLR = -105.15. Another example of comparisons between different children in the same grade is illustrated in Fig. 9. The three pairs of images are from the same two children, HUA2022CH and IAC2022SA, in grades 2–4, respectively. Comparing each pair, we get low LLR values of -18.64, -101.99, and -178.74, which are smaller with each higher grade.

To determine statistical significance, we use the chi-squared goodness-of-fit test, to compare different distributions (12). The data are divided into bins, which have at least 5 elements in each of them. Then, the test statistic is calculated as follows:

$$\chi^2 = \sum_{i=1}^k (O_i - E_i)^2 / E_i$$

where k is the number of bins, O_i and E_i are the frequency count for the i^{th} bin of the two distributions. The test statistic follows a chi-squared distribution. Therefore, the null hypothesis that the two distributions are consistent is rejected if the calculated test statistic χ^2 is larger than the chi-squared critical value, which can be determined in a chi-squared distribution table with $k - 1$ degrees of freedom and significance level α .

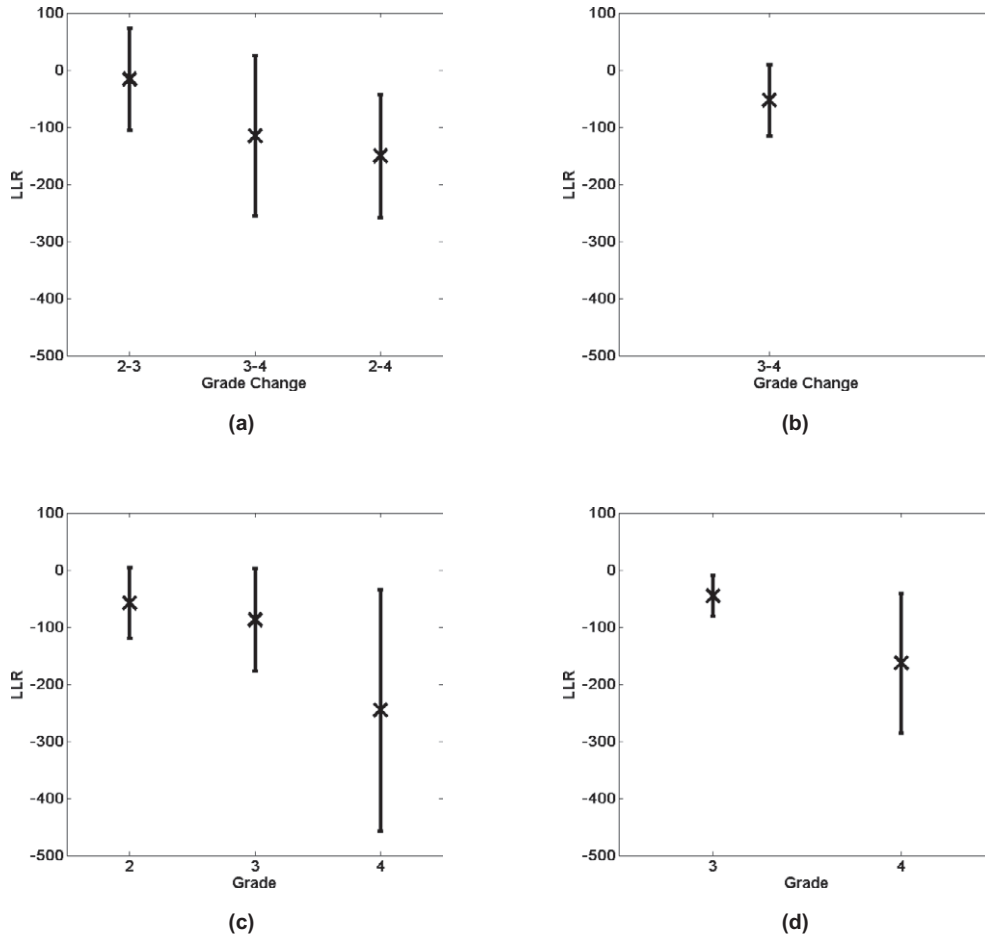

FIG. 7—Distributions of LLRs: (a) same child from different grades in handprinted, (b) same child from different grades in cursive, (c) different children in grades 2–4 in handprinted, and (d) different children in grades 3–4 in cursive.

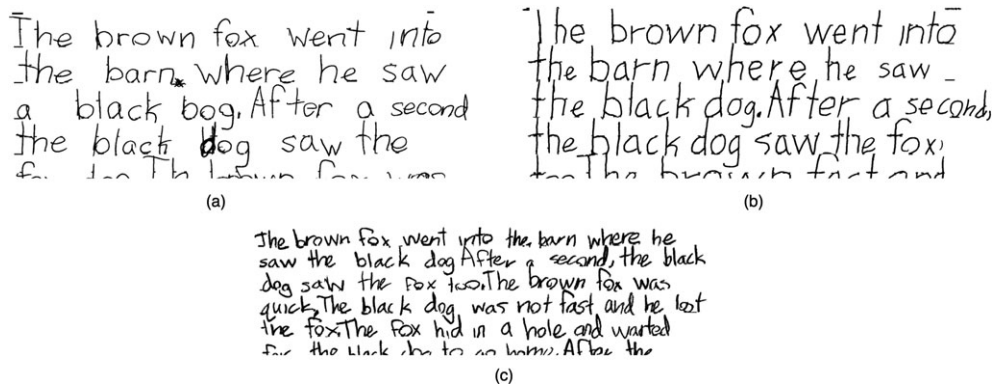

FIG. 8—Handprinted samples for the same child in three grades: (a) grade 2 in 2011–2012, (b) grade 3 in 2012–2013, and (c) grade 4 in 2013–2014. Between grades 2–3, LLR = 51.71 indicating high similarity, while between grade 3–4 and 2–4, LLR = -105.15 and -148.05 indicating less similarity.

We used the chi-squared goodness-of-fit test for three kinds of comparisons of LLR values: (i) between different grades’ handprinted results, (ii) between different grades’ cursive results, and (iii) between the two kinds of writing styles in the same grade. Through the test, we get the test statistic for the null hypothesis $H_0 =$ same distribution, as shown in Table 5. According to the chi-squared distribution table with $\alpha = 0.05$, the null hypothesis of same distribution is rejected. Thus, we conclude that all of the compared result distributions are statistically different.

The results for different schools are also tabulated. Comparison of the same child’s handwriting in two consecutive years is shown in Table 3. The average LLR between grades 2 and 3 for handprinted writing is -15.85 showing some change, but between grades 3 and 4, it is -115.05 indicating a much more marked difference. As for cursive writing between grade 3 and grade 4, the average LLR value is -52.85. LLR values when different grade 2 children are compared are summarized in Table 4. The mean of -57.69 is much larger than the mean of

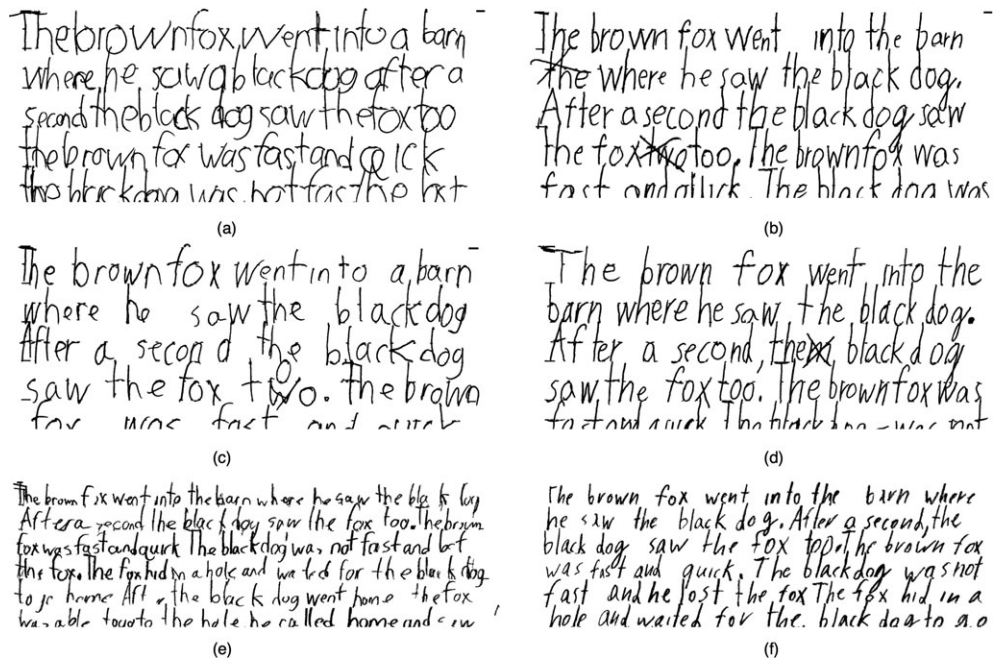

FIG. 9—Handprinted samples of two different children: (a, b) in grade 2 with LLR = -18.64, (c, d) in grade 3 with LLR = -101.99, and (e, f) in grade 4 with LLR = -178.74.

$G_{3,4}^{sh}$ versus $G_{3,4}^{sc}$	1.38e+03	Yes
G_3^{dh} versus G_4^{dc}	2.08e+03	Yes
G_4^{dh} versus G_4^{dc}	565.86	Yes

$G_{i,j}^{sh}$ = Comparison of handprinted of same child for grade i and j .

$G_{i,j}^{sc}$ = Comparison of cursive of same child for grade i and j .

G_i^{dh} = Comparison of handprinted of different children for grade i .

G_i^{dc} = Comparison of cursive of different children for grade i .

-15.85 in Table 3 for grade pair 2 and 3, implying that different children in the same grade write more differently from each other when compared to the same child in different grades.

Table 4 also summarizes comparisons between pairs of different children in grades 3 and 4. The mean values of -87.17 and -245.16 for handprinted writing, and -45.12 and -162.98 for cursive writing, indicate that children write more differently as they grow up. Consistently, in Fig. 7(a), the cross on the second vertical line is lower than the one on its left. This shows that when comparing handprinted writings from the same child in different years, the mean LLR of grades 3 to 4 has a larger absolute value than the mean LLR of grades 2 to 3. This also indicates children change their handwriting to a larger degree from grade 3 to 4 than from grade 2 to 3. The crosses in Fig. 7(c) and Fig. 7(d) refer to the means for different children. Observing

the three crosses in Fig. 7(c), which are for handprinted writings in grades 2, 3, and 4, or the two in Fig. 7(d), which are for cursive writings in grade 3 and 4, we see that both are progressively lower.

The standard deviations, which represent the amount of variation of the data from its average, are also interesting to observe. They are tabulated as well as indicated by the lengths of the vertical lines in Fig. 7. For the comparisons of the same child, the degree of dispersion is more when children move from grade 3 to 4 than from grade 2 to 3. For the comparisons between different children, dispersion is more for higher grades.

Conclusion for Approach 2

We compared both handprinted and cursive handwriting samples of children progressing from grades 2 to 4. We considered the entire writing sample image as input and compared it another writing image thereby yielding an LLR value for each comparison. The distribution of LLR values for each pair of grades was compared to the distribution for another pair of grades using the chi-squared goodness-of-fit test and found to be different. Analysis of the mean and variance of LLRs between writing samples of different children indicates higher differences as grades progress.

Discussion

We have presented two temporal analyses of handwriting of children as they progressed from grade 2 to 4. The first analysis was of characteristics of the frequently occurring word *and*. The characteristics, which were specified by FDEs, were 12 in number with each characteristic taking one of several discrete values for a given writer. Probability distributions of the characteristics for each grade were compared, using relative entropy, to determine how the populations changed over the years. As measured by relative entropy, there was a smaller difference between grades 2 and 3 than between grades 3 and 4.

The second analysis was based on a paragraph of text (seven sentences). The handwritten paragraphs were scanned and used in an automated system, which can obtain a score, log-likelihood ratio (LLR), between a pair of handwriting samples. As measured by LLR, there was a smaller difference between grades 2 and 3 than between grades 3 and 4.

Both types of analyses came to the same conclusion: As children move to higher grades, differences in writing styles increase. This provides another justification for handwriting individuality, that handwriting becomes more individualistic with age even when children are taught with the same writing style.
